Smith-Magenis Syndrome (SMS): SMS involves head malformation, short brain, growth retardation, hearing loss, and self-destructive behavior, such as pulling off nails, inserting foreign objects into the ear, etc. The incidence is $>4 \times 10^{-5}$. In 80–90% of the patients, an approximately 4 Mb interstitial deletion heterozygosity is found at the chromosome 17p11.2 region. The locus contains or is flanked by low-copy number repeats, which favor the occurrence of localized recombinations that generate deletions and duplications (Bi W et al 2003 Am J Hum Genet 73:1302). In individuals without cytologically detectable deletions, a 29 nucleotide loss was observed in exon 3 of the RAI1 (retinoic acid induced, 17p11.2) gene. ►mental retardation, ►self-destructive behavior; Slager RE et al 2003 Nature Genet 33:466.

Smith-McCort Dysplasia: ►Dyggve-Melchior-Clausen dysplasia

Smith-Waterman Algorithm: Computer analysis for nucleic acid sequences (Waterman MS 1988 Methods Enzymol 164:765).

SMM: ►stepwise mutation model, ►IAM, ►two-phase model

Smoking: Smoking is responsible for a wide variety of ailments such as heart disease, respiratory problems, cancer, etc., but it may decrease the risk of Parkinson's disease. The inhalation of tobacco smoke by the mother may initiate cancer also in the fetus. Although cancer may be induced by a variety of genotoxic agents in the environment, the smoking induced alteration spectrum in the genetic material is different and thus can be distinguished from the effects of other agents. Tobacco smoke adducts induce a higher proportion of transversion mutations of the p53 gene in the lung and also increases loss of heterozygosity by deleting introns particularly at the fragile site 3 (FRA3B) region including FHIT (fragile histidine triad) in human chromosome 3p14.2. According to one report, 19/31 newborns of smoking mothers had the carcinogen 4-methylnitrosamino-1-(3-pyridyl)-1-butanone in their urine.

The smoking habit is particularly prevalent in affective disorders. In the brain of smokers, the level

of monoamine oxidase B (MAOB) is 40% lower relative to that in non-smokers. MAOB degrades the neurotransmitter dopamine. Subcortical regions, such as the amygdala, the nucleus accumbens, and the mesotelencephalic dopamine system, have been shown in animal models to promote the self-administration of drugs of abuse. Functional imaging studies have shown that exposure to drug-associated cues activates cortical regions such as the anterior cingulate cortex, the orbitofrontal cortex, and the insula. In nicotine addiction, the insula, a narrow island within the brain, seems to play a critical role; persons with disrupted insula are more likely to be able to quit the addiction without relapse (Naqvi NH et al 2007 Science 315:531). The nicotinic acetylcholine receptors play, however, very important roles in the cognitive processes of the brain. Tolerance to smoking seems to be influenced by diet and ethnic background. The carcinogenic effect of smoking tobacco is primarily due to specific N-nitrosamines. Second hand smoking may also stimulate angiogenesis and thus tumor growth (Zhu B et al 2003 Cancer Cell 4:191). ►Parkinson's disease, ►dopamine, ►affective disorders, ►nicotinic acetylcholine receptors, ►nicotine, ►transversion, ►intron, ►fragile site, ►p53, ►chemical mutagens, ►tobacco, ►MAO, ►infertility, ►mortality, ►small cell lung carcinoma; Hecht SS 1999 Mutat Res 424:127; Schuller HM 2002 Nature Rev Cancer 2:455; environmental exposure: Besaterina A et al 2002 Carcinogenesis 23:1171; Allan M Brandt AM 2007 The Cigarette Century. The Rise, Fall, and Deadly Persistence of the Product that Defined America. Basic Books, New York; effect on respiratory tract genes: <http://pulm.bumc.bu.edu/siegeDB>.

Smooth Endoplasmic Reticulum: The smooth endoplasmic reticulum has no ribosomes on its surface. ►SER, ►endoplasmic reticulum

Smooth Muscle: Smooth muscles lacks sarcomeres; they are associated with arteries, intestines, and other internal organs, except the heart. ►sarcomeres, ►striated muscles

SMRT: A silencing-mediator of retinoid and thyroid hormone receptors. It is also corepressor of PPAR δ . ►retinoic acid, ►animal hormones, ►nuclear receptors, ►PPAR; Becker N et al 2001 Endocrinology 142:5321.

Smut: Infection of grasses by *basidiomycete* fungi, causing black carbon-like transformation of the inflorescence (by *Ustilago*, loose smut) or seed tissues (by *Tilletia*, covered smut).

Snail: *Helix pomatia univalens*, 2n = 24.

Snail: A family of zinc-finger transcription factors and a negative regulator of E-cadherin. ▶[cadherin](#); Bettle E et al 2000 *Nature Cell Biol* 2:84; Nieto MA 2002 *Nature Rev Mol Cell Biol* 3:155.

Snakes: Reptiles represented by a large number of cosmopolitan species of diverse sizes up to 30 ft in length. Generally, they do not have legs, except some vestigial remnants in a few species. They use their protruding tongues to smell the environment. Their heat-sensory organs are located between the eyes and the nostrils, are highly sensitive, and are used to detect potential prey. Their teeth (fangs) with grooves conduct their venom to the body of the prey. The venom sacs (in the venomous species) are modified from the salivary gland. Snakes are carnivorous. Their sexual organs are located at the end of the cloaca (alimentary channel). Fertilization is internal but the eggs are laid in the environment, although in some species the eggs hatch within the female body. Snake venom is used primarily for killing the prey. The prey is swallowed when dead, without chewing. Snake protein venoms are very diverse and have evolved from acetylcholinesterase, ADAM, AVIT, complement C3, crotoxin/β-defensin, cystatin, endothelin, factor V, factor X, kallikrein, Kunitz-type proteinase inhibitor, LYNX/SLUR, L-amino oxidase, lectin, natriuretic peptide, β-nerve growth factor, phospholipase A₂, SP1a/Ryanodine, vascular endothelial growth factor, and whey acidic protein/secretory leukoproteinase inhibitor (Fry BG 2005 *Genome Res* 15:403). Knowledge of the physiological/molecular nature of these proteins has evolutionary interest and is important because of its therapeutic relevance.

Snake Venom Phosphodiesterase: Snake venom phosphodiesterase releases 5'-nucleotides from the 3' end of nucleic acids. ▶[phosphodiester bond](#), ▶[phosphodiesterases](#)

S

Snap: ▶[NSF](#), ▶[membrane fusion](#), ▶[SNAREs](#)

Snap-Back: Inverted repeat sequence in nucleic acids. ▶[repeat inverted](#), ▶[lollipop structure](#)

Snapdragon (*Antirrhinum majus*): 2n = 16, a dicotyledonous plant (*Scrophulariaceae*) much employed for the study of mutation (transposable elements) and flower pigments. It is also a popular ornamental. Snapdragon also has many beautiful flower morphology mutants as shown. ▶[TAM](#), ▶[Antirrhinum](#), ▶[peloric](#), flower morphology mutants at ▶[mutation spectrum](#); Schwarz-Sommer Zs et al 2003 *Nature Rev Genet* 4:655; <http://www.antirrhinum.net/>.

SNAREs (soluble N-ethylmaleimide-sensitive factor attachment protein receptor): Binding protein attaching vesicles (v-SNAREs) to target membranes (t-SNAREs) (see Fig. S77).

They mediate, among others, transport through the Golgi compartments. SNAREs also mediate membrane fusions, alongwith plant cell wall penetration resistance to fungal pathogens on normally non-host species. (Collins NC et al 2003 *Nature [Lond]* 425:973). The name has been attributed to surgical wire tools, by which polyps and projections are removed. It could also be linked with bird traps (snare). SNARE seems to be activated by Ypt1p. ▶[NSF](#), ▶[RAB](#), ▶[EEA1](#), ▶[Ypt](#), ▶[snare](#), ▶[synaptobrevin](#), ▶[VAMP](#), ▶[syntaxin](#), ▶[synaptogamin](#), ▶[NSF](#), ▶[Golgi apparatus](#), ▶[membrane fusion](#), ▶[exocytosis](#), ▶[Munc1](#), ▶[Ipk1](#); Bock JB, Scheller RH 1999 *Proc Natl Acad Sci USA* 96:12227; Peters C et al 2001 *Nature [Lond]* 409:581.

SNF: SNF yeast genes are helicases involved in chromatin remodeling (*SNF2*, *SNF5*, *SNF6*, *SNF11*) and *SNF1* is an AMP-activated kinase. SNF1 senses depletion of ATP and increase of AMP in the cell. This is a ubiquitous enzyme family involved in carbohydrate and lipid metabolism, phosphorylation of transcription factors, regulating stress responses in plants, etc. An SNF-6 protein is an acetylcholine transporter in *Caenorhabditis* (▶[muscular dystrophy](#)). ▶[chromatin remodeling](#), ▶[SWI](#), ▶[SUC2](#), ▶[bromodomain](#); Eisen JA et al 1995 *Nucleic Acids Res* 23:2723; Lo W-S et al 2001 *Science* 293:1142.

SNIPs (single nucleotide polymorphism, SNP): SNPs refer to the difference in a single nucleotide at a particular DNA site; these are used as genomic

Figure S77. SNARE

markers for human (or other) populations. The most common variation involves C \leftrightarrow T transition in CpG sequences. The analysis uses DNA chips or gel-based sequencing and biotin-labeled probes (VDA, variant detector array). Several different methods exist for the detection of SNPs.

The presence of a single mismatch decreases the electrochemical potential of the DNA. On this basis, transitions and transversions can be detected by the electrochemical response (Inouye M et al 2005 *Proc Natl Acad Sci USA* 102:11606). A survey of 2748 SNPs indicated high degree of polymorphism (4.58×10^{-4}) and mutation rate $\mu \sim 10^{-8}$ to the range of about 10% of the confirmed SNPs. Other estimates for average nucleotide diversity (π) were higher: 9.01×10^{-4} for African-Americans and 6.97×10^{-4} for European-Americans (Crawford DC et al 2005 *Annu Rev Genomics Hum Genet* 6:287). Other studies indicated one SNIP/600 base pairs in the human genome (Kruglyak L, Nickerson DA 2001 *Nature Genet* 27:235). The annotated human chromosome 6 (166,880,988 bp) contains 2761 SNPs in the protein-coding genes (Mungall AJ et al 2003 *Nature [Lond]* 425:805).

SNPs can be mapped to chromosomal location by radiation hybrid cell lines. If the SNP is not within the gene, recombination may lead to false positive identification. SNPs can be generated for the identification of the critical base substitutions responsible for human disease. The majority of SNPs occur in non-coding regions of the genome and are non-informative regarding human disease (Sachidanandam R et al 2001 *Nature [Lond]* 409:928). Some SNPs in non-coding regions may, however, regulate gene expression.

Mapping of SNPs can be carried out by the reduced representation shotgun sequencing (RRS) and by locus-specific polymerase chain reaction amplification (LSA).

Frequently within a gene or within a haplotype, several SNPs exist and several of them may contribute to the disease phenotype. In order to determine their significance for a disease, their location within the haplotype requires mapping (see Fig. S78) (Carlson CS et al 2004 *Am J Hum Genet* 74:106; Livingston RJ et al 2004 *Genome Res* 14:1821). If polony amplification is used from a buccal smear, a single microscope slide permits appropriate genotyping (Mitra RD et al 2003 *Proc Natl Acad Sci USA* 100:5926).

However, when many special cases of the same disease are analyzed, the significance of the base substitutions may be statistically or even causally determined (see Fig. S79). Generally, the number of SNPs is much higher in introns than in exons. For population genetics and linkage studies, the SNPs are frequently classified into types I (involving

Figure S78. Two-nucleotide deletion in the ABC1 transporter gene results in Tangier disease. Note the frame-shift. (Courtesy of H. Bryan Brewer, Jr. Modified after Remaley AT et al 1999 *Proc Natl Acad Sci USA* 96:12685)

non-synonymous alterations regarding its coding property and being a non-conservative change), II (within coding region and non-synonymous yet conservative), III (in coding sequence but synonymous), IV (within the non-coding 5' sequence), V (within the non-coding 3' sequence), or VI (in other non-coding regions). The type I SNPs are most useful for genetic analyses because they have phenotypic (functional) characteristics. Preliminary information indicates that the majority of the SNIP haplotypes ($\sim 80\%$) occurs in all ethnic groups and only 8% are population-specific (Patil N et al 2001 *Science* 294:1719). MALDI analysis applied to SNPs may facilitate the analysis of QTLs (Mohlke KL et al 2002 *Proc Natl Acad Sci USA* 99:16928). By March 2001, 2.84 million SNPs had been deposited in the public databases and they represented 1.64 million non-redundant mutations (Marth G et al 2001 *Nature Genet* 27:371). The human SNP map includes an ever-increasing number (~ 8 million by 2005; actually 6 million are validated by 2007) of variants of the world population (<http://www.hapmap.org>). Regulatory SNPs were detected in the germline of several breast cancer genes controlling the somatic function, the reactive oxygen species (ROS) pathway (Kristensen VN et al 2006 *Proc Natl Acad Sci USA* 103:7735). ▶allele, ▶DNA chips, ▶MALDI/TOF/MS, ▶genotyping, ▶MRD, ▶radiation hybrid, ▶STS, ▶QTL, ▶RRS, ▶LOS, ▶biotinylation, ▶DASH, ▶DNA repair, ▶padlock probe, ▶linkage disequilibrium, ▶association test, ▶polony, ▶haplotype, ▶giSNP, ▶haplotype block, ▶Tangier disease, ▶breast cancer, ▶ABC transporters, ▶allele-specific

SNO Oncogenes: Two SKI-related oncogenes. ►SKI, ►oncogene

Snorbozyme: A ribozyme within the nucleolus, processing or degrading nucleolar RNA. (See Samarsky DA et al 1999 Proc Natl Acad Sci USA 96:6609).

snoRNA (small nucleolar RNA): snoRNA is 60–300 nucleotide in length and assists in maturation of ribosomal RNAs in the nucleolus, the folding of RNA, RNA cleavage, base methylation, assembly of pre-ribosomal subunits, export of RNP, etc. A family of snoRNAs of 10–21 nucleotides, complementary to the methylation sites of rRNA, guides the methylation within the nucleolus. Some of the snoRNA genes are situated in introns. The majority of the snoRNAs are either box C/D or H/ACA snoRNA family members. All CD boxes contain fibrillarin and (spliceosomal) Snu13. They are apparently involved in splicing and alternative splicing (Kishore S, Stamm S 2006 Science 311:230). ►RNA maturase, ►pseudouridine, ►introns, ►fibrillarin, ►spliceosome, ►non-coding RNA; Hirose T, Steitz JA 2001 Proc Natl Acad Sci USA 98:12914; Song X, Nazar RN 2002 FEBS Lett 523:182; snoRNA database: <http://www-snoRNA.bio.toul.fr>; snoRNA and Cajal body-specific RNA: <http://gene.fudan.sh.cn/snoRNAbase.nsf>.

Snowdrift Game: One of the theories of evolutionary population dynamics and natural selection. An oversimplified analogy for the principle is that of drivers trapped on either side of a snowdrift. The drivers can either cooperate and both start clearing the road from opposite sides or one of them fails to work (defects). In case of cooperation, they benefit (b) by sharing the

labor (c). The result is $R = b - c/2$. If both defect, the probability to get through is $P = 0$. If only one works, they can both get through, but the defector avoids the cost of labor and gets all the benefits ($b - c$). ►prisoner' dilemma; Hauert C, Doebeli M 2004 Nature [Lond] 428:643; Nowak MA et al ibid. p 646.

SNP: ►SNIPS

snRNA (small nuclear RNA): Low molecular weight RNA in the eukaryotic nucleus, rich in uridylic residues. When associated with protein, sRNA mediates the splicing of primary RNA transcripts and frees them from introns through assistance of the lariat. The spliceosomal snRNP can be exported to the cytoplasm if appropriately capped, i.e., if it possesses the nuclear cap-binding complex, the export receptor CRM1/Xpo1. RanGTP and the phosphorylated adaptor of RNA export (PHAX) are also required for this process. ►hnRNA, ►U1-RNA, ►RNP, ►Ran, ►CRM1/SXPO1, ►export adaptor, ►introns, ►spliceosome, ►lariat, ►Ohno's law, ►7SK RNA; M et al 2000 Cell 101:187; Kiss T 2001 EMBO J 20:3617; 2002 Gene Expr 10(1/2).

snRNP: Small nuclear ribonucleoprotein, (also pronounced as “snurp”). It is involved in the processing of RNA and the assembly of spliceosomes. ►KH domain, ►imprinting, ►spliceosome; Nagengast AA, Salz HK 2001 Nucleic Acids Res 29:3841.

Snurportin: An α importin-like transport protein handling snRNP import to the cell nucleus. ►importin, ►nuclear pore, ►snRNP; Paraskeva E et al 1999 J Cell Biol 145:255.

Snurposomes: A complex of the five snRNP particles (“snurps”) that process RNA transcripts in the Cajal bodies. ►U RNAs, ►Cajal body, ►coiled body; Gall JG et al 1999 Mol Biol Cell 10:4385.

SOAP (Simple Object Access Protocol): <http://www.w3.org/TR/soap/>.

SOB Bacterial Medium: The SOB bacterial medium consists of: H₂O 950 mL, bacto tryptone 20 g, bacto yeast extract 5 g, NaCl 0.5 g plus 10 mL of 250 mM KCl; its pH is adjusted to 7 with 5 N NaOH in a total volume of 1 L. Just before use add 5 mL of 2 M MgCl₂.

SOC (store-operated channel, synonym: TRP transient receptor potential): a group of plasma membrane ion channels controlling the release of ions stored in the lumen of the endoplasmic reticulum. ►ion channels; Ma R et al 2001 J Biol Chem 276:25759.

SOC Bacterial Medium: The same as SOB but contains glucose (20 mM). ►SOB

Social Darwinism: The application of Darwinian views (survival of the fittest) to social order. Many anthropologists, sociologists, and ethicists rejected social darwinism and portend that it is an attempt to justify inequalities, harsh competition without adherence to ethics, aggression, imperialism, racism, and unbridled capitalism as necessities for the survival of the fittest. Social darwinism of the 19th century is no longer accepted in the developed world. ▶[Darwinism](#), ▶[IQ](#), ▶[social engineering](#); Rogers JA 1972 *J Hist Ideas* 33:265.

Social Engineering: The Utopian idea that the genetic determination of an individual is unimportant in defining the abilities and their realization but education, welfare, medical service, etc., may determine how a person will function in a society. Therefore, the state and its institutions must actively control human life from cradle to death. However, even though the importance of compassion, education, caring, and multiple social safety nets are indispensable in a modern society, the significance of individuality cannot be ignored. ▶[social Darwinism](#), ▶[IQ](#); Graebner W 1980 *J Am Hist* 67:612.

Social Insects: Insects like bees, wasps, ants, and termites that live in a colony and generally divide various tasks among different castes, such as workers (soldiers), queen, and drones. The queen (gyne) and the workers and soldiers are diploid. In some species, the workers may produce males. The drones are different because they hatch from unfertilized eggs. The major differences between the queen and the workers is that the queens have predominantly 9-hydroxy-(*E*)2-decanoic acid and 9-keto-(*E*)2-decanoic acid in their mandibular glands. The workers have predominantly 10-hydroxy-(*E*)2-decanoic acid. These pheromones then determine their respective functional roles in the colony. The workers and soldiers have ovaries and under certain circumstances (especially the soldiers) may produce haploid eggs. Cuticular hydrocarbons may regulate sex expression and convert workers into egg-laying females (gamer-gate), although usually smaller in size. Such a change in some groups may take place by physical contact of individuals transmitting the hydrocarbon molecules. Recently, the status of soldiers has been questioned as being genetically equivalent with the workers. The soldiers' (not found in all species of social insects) role is protection of the colony. In the fire ant *Wasmannia auropunctata*, a widely distributed species, sex determination is unique. The queens produce other queens clonally (without sexual reproduction). The diploid sterile workers are the products of sexual reproduction. The males are derived from unfertilized eggs containing only the paternal genome (the maternal genome is eliminated

from the diploid eggs). Therefore, the male and female genomes are completely separated (Fournier D et al 2005 *Nature [Lond]* 435:1230). ▶[sex determination](#), ▶[male-stuffing](#), ▶[ant](#), ▶[honey bee](#), ▶[wasp](#); Bourke AF 2001 *Biologist [Lond]* 48(5):205; Parker JD, Hedrick PW 2000 *Heredity* 85(pt 6):530; Thorne BL, Traniello JFA 2003 *Annu Rev Entomol* 48:283; development of caste differences: Hoffman EA et al 2007 *BMC Biol* 5:23.

Social Selection: Social selection is not based on Darwinian fitness but on the social status of the individual carrying the trait. A particular Y-chromosome is found in a large region from the Pacific to the Caspian Sea where the Mongols of Genghis Khan ruled. It originated about the same time—about 1000 years ago—as the Mongolian Empire. Thus, the rapid spread of this chromosome may be due to the social privileges of the carriers. Preimplantation selection of the sex of human offspring is also called social selection. Its purpose can be the avoidance of defective children caused by chromosomal anomalies and hereditary disease. Family balancing, i.e., having children in a certain proportion of boys and girls is generally an ethically unacceptable goal. In the USA, many institutions object to it and refuse the medical procedure required. ▶[Y chromosome](#), ▶[sex selection](#); Zerjal T et al 2003 *Am J Hum Genet* 72:717.

Sociobiology: The study of the biology and behavior of social insects and other animal communities. ▶[social insects](#); Wilson EO 2000 *Sociobiology: The new synthesis*. Harvard University Press, Cambridge, Massachusetts.

Sociogenomics: Sociogenics studies the genetic and molecular biology of the functions involved in social life. ▶[kin selection](#), ▶[altruism](#), ▶[mutualism](#); Robinson GE et al 2005 *Nature Rev Genet* 6:257.

SOCS-Box (suppressor of cytokine signaling): The SOCS-box contains a protein docking site(s) for protein-protein interaction and seems to be involved in transduction signal attenuation and ubiquitination. SOCS-2^{-/-} mice display greatly increased body weight caused apparently by inappropriate regulation of the Jak/Stat signal transduction and the IGF-I pathways. ▶[cytokine](#), ▶[signal transduction](#), ▶[CIS](#), ▶[JAB](#), ▶[SSI-1](#), ▶[CSAID](#), ▶[ubiquitin](#), ▶[insulin-like growth factors](#); Zhang JG et al 2001 *Proc Natl Acad Sci USA* 98:13261.

SOD (superoxide dismutase): ▶[superoxide dismutase](#), ▶[amyotrophic lateral sclerosis](#)

SODD: ▶[TNFR](#)

Sodium Azide (N_3Na): An inhibitor of respiration that blocks the electron flow between cytochromes and O_2 . It is also a potent mutagen for organisms that can activate it.

Sodium Channel: ► [ion channels](#)

Sodium Dodecyl Sulfate: A synonym for sodium lauryl sulfate; ► [dodecyl sulfate sodium salt](#)

Sodium Pump: A plasma membrane protein that moves Na^+ out and K^+ into the cells with the energy obtained by hydrolyzing ATP; it is also called Na^+/K^+ ATPase. ► [ion channels](#)

Soft Inheritance: Soft inheritance has been a rather controversial notion; its theory claims that environmental influences mold heredity and acquired characters are inherited. ► [acquired characters](#), ► [hard heredity](#) of inheritance of acquired characters, Lamarckism, Neo-Lamarckism, Lysenkoism, and other ideas claiming that environmental factors modify the genetic material at a non-random manner (not including mutation or transformation) but by direct manner shaping adaptive traits. Epigenetics has shown however that some traits are transmitted to the progeny by their acquired status of methylation. (See terms in alphabetical order, ► [hard heredity](#)).

Software: A computer program that tells the hardware (the computer) the applications, i.e., which instructions to carry out and how. ► [databases](#); <http://www.sanger.ac.uk/Software/Pfam/>.

Sog: ► [bone morphogenetic protein](#)

Soil Remediation: Soil remediation involves the removal of environmental pollutants from soil and water. It requires sensitive identification of small amounts of toxic and carcinogenic and mutagenic substances, such as arsenic, heavy metals, polycyclic hydrocarbons, etc. ► [arsenic](#), ► [phytoremediation](#), ► [DNAzyme](#)

Solenoid Structure: A coiling electric conductor used for the generation of a magnetic field; by analogy, the coiled nucleosomal DNA fiber is frequently described as a solenoid, although it has no relation to electricity or magnetism. It merely resembles those coils. The DNA solenoids are about 30 nm in diameter, contain about six nucleosomes per turn, and are packed with a large number of structural and catalytic proteins. Actually two different models have been proposed for the 30 nm solenoid structure of the chromosome sub-fibers although neither of them has been fully and universally confirmed. One has been based on the crystal structure of a four-nucleosome core array lacking the linker histone and the other, far more compact structure, has been derived from the electron microscopic analysis of long nucleosome

arrays containing the linker histone. The first model is of the two-start helix type, the second a one-start helix with interdigitated nucleosomes. Both of these models assume that the fiber is regulated by histones (Robinson PJ, Rhodes D 2006 *Curr Opin Struct Biol* 16:336; Tremethick DJ 2007 *Cell* 128:651). ► [nucleosome](#), ► [nuclear matrix](#), ► [zig-zag model of chromosome fibers](#)

Solid Phase Synthesis: In a solid-phase synthesis, the synthesized molecules are continuously added to a solid support.

Solid State Control: Solid state control is exercised by electric or magnetic means in solids, e.g., in a transistor. ► [semiconductors](#)

Solitary LTR: Long terminal repeats that have lost their internal (transposase) sequences by re-combination and excision. ► [long terminal repeats](#), ► [retrovirus](#), ► [retroposon](#), ► [retrotransposon](#); Domansky AN et al 2000 *FEBS Lett* 472(2–3):191.

Solo Elements: Terminal sequences (LTR) of retroposons that can exist in multiple copies without the coding sequences between the two direct repeats. ► [Ty](#)

Soluble RNA: A somewhat outdated term for transfer RNA. ► [tRNA](#)

Solute: Any substance dissolved in a solvent.

Solution Hybridization: Molecular hybridization in a liquid medium. ► [nucleic acid hybridization](#)

SOM (self-organizing map): A type of mathematical cluster analysis that is particularly well suited for recognizing and classifying features in complex, multidimensional data of microarray hybridization. The method has been implemented in a publicly available computer package, GENECLUSTER, that performs the analytical calculations and provides easy data visualization. ► [microarray hybridization](#), ► [cluster analysis](#); Sinha A, Smith AD 1999 *Microgravity Sci Technol* 12(2):78; Haese K, Goodhill GJ 2001 *Neural Comput* 13:595; Unneberg P et al 2001 *Proteins* 42:460.

Soma: Body cells distinguished from those of sexual reproduction (germinal cells). ► [disposable soma](#)

Somaclonal Variation: Genetic variation occurring at a frequency higher than spontaneous mutation in cultured plant cells (see Fig. [S80](#)). (See Kaeppler SM et al 2000 *Plant Mol Biol* 43(2–3):179).

Figure S80. Mitotic anomalies in a clone of tobacco maintained in cell culture. (a), (b) anaphase bridges, (c) telophase bridge, (d) the same as (c) but enlarged nuclei, (e) early interphase with conjoined nuclei. Polyploidy is also of common occurrence. (From Cooper LS et al 1964 Am J Bot 51:284)

The causative mechanism is poorly understood. It is conceivable that the asynchrony between nuclear and cell divisions are accompanied by chromosomal damage. Also, there is evidence that movement

of endogenous transposable elements is involved. The mobility is attributed to the “stress” imposed by the culture (see Fig. S81).

Somatic Cell: The majority of the body cells (reproduced by mitosis), including those of the germline but not the products of meiosis, the sex cells (gametes).
 ▶germline, ▶cell lineages, ▶mitosis, ▶cell genetics, ▶parasexual mechanisms

Somatic Cell Hybrids: Somatic cell hybrids are formed through fusion of different somatic cells of the same or different species. Somatic cell hybrids contain the nucleus of both cells and in addition all cytoplasmic organelles from both parents, in contrast to the generative hybrids where generally mitochondria and plastids are not transmitted through the male.

For the fusion of cultured somatic cells, the use of various special techniques is necessary. Most commonly, protoplasts are used and the fusion medium is:

Figure S81. Selective isolation of mouse + human cell hybrids. The fused cell usually retains all mouse chromosomes but the human fibroblast chromosomes may be partially eliminated and in some clones only one or another human chromosome is maintained. (Modified after Ruddle FH, Kucherlapati RS 1974 Sci Am 231(1):36)

polyethylene glycol [MW 1300–1600] 25 g, $\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$ 10 mM, KH_2PO_4 0.7 mM, glucose 0.2 M in 100 mL H_2O , pH 5.5 for plants. The best media may vary according to species. The isolation of somatic animal cell hybrids was greatly facilitated by using selective media (see Fig. S82). (►HAT medium).

The fusion of animal cells is promoted by polyethylene glycol, by attenuated Sendai virus, or by calcium salts at higher pH. Immediately after fusion, the somatic cells may become heterokaryotic but eventually the nuclei may also fuse. The availability of fused cells along with loss of one set of chromosomes or partial deletion of chromosomes make possible the localization of many human genes (see Fig. S84). In human genetics, mouse + human cells have been used most commonly. In such cultures, the human chromosomes are gradually eliminated. However, if one of the mouse chromosomes carries a defective gene, the human chromosome carrying a functional wild type

Figure S82. Selective isolation of animal somatic cell hybrids deficient in thymidine kinase and hypoxanthine-guanine phosphoribosyltransferase. On “HAT” medium only the complementary heterokaryons survive. (Modified after Ephrussi B, Weiss MC 1969 Sci Am 220 (4):26)

| | | Human chromosomes | | | | | | | |

Figure S83. Chromosome assignment of genes on the basis of incomplete clones of mouse + human cell hybrids. A panel of 3 clones, each containing a set of 4 of 8 human chromosomes. If a gene is expressed uniquely in clone (C) but not in (A) or (B), the locus must be in chromosome 7. Because only C carries chromosome 7. Additional panels are needed to test genes in the entire human genome. (After Ruddle FH, Kucherlapati RS 1974 Sci Am 231(1):36)

Figure S84. Regional mapping of the thymidine kinase (TK) gene to a segment of human chromosome 17. A translocation was obtained between human chromosome 17 and a mouse chromosome that was deficient for TK. The translocation chromosome was exposed to a chromosome-breaking agent that cleaved off segments of various lengths from the end of the translocation. When the segment containing the gene (TK) was removed, the cells carrying this broken chromosome no longer displayed TK activity and the gene's location was revealed at 17q23.2-q25.3. (►human chromosome map; Modified after F.H. Ruddle and R.S. Kucherlapati)

allele must be retained in order that the culture be viable in the absence of a particular supplement, required for normal function (see Fig. S83). The genetic constitution of the retained human chromosome can be also verified by enzyme assays, electrophoretic analysis of the proteins, or immunological tests. For genetic analysis of higher mammals, and particularly in humans, where controlled mating is not feasible, the availability of somatic hybrids has opened a new and very productive approach. In the somatic hybrid cells, allelism and also synteny or linkage can be shown. If two or more human genes are consistently expressed in a particular chromosome retained, it is a safe conclusion that they are located in the same chromosome. The diagram (see Fig. S83) explains the principle

of gene assignment. Genes can be mapped to particular chromosome bands by deletions. By somatic cell fusion, hybrids can be obtained between taxonomically very distant species.

All kinds of animal cells may be fused with each other, and in addition plant and animal cells can also be fused. Some of these exotic hybrids may have, however, difficulties in continuing cell divisions.

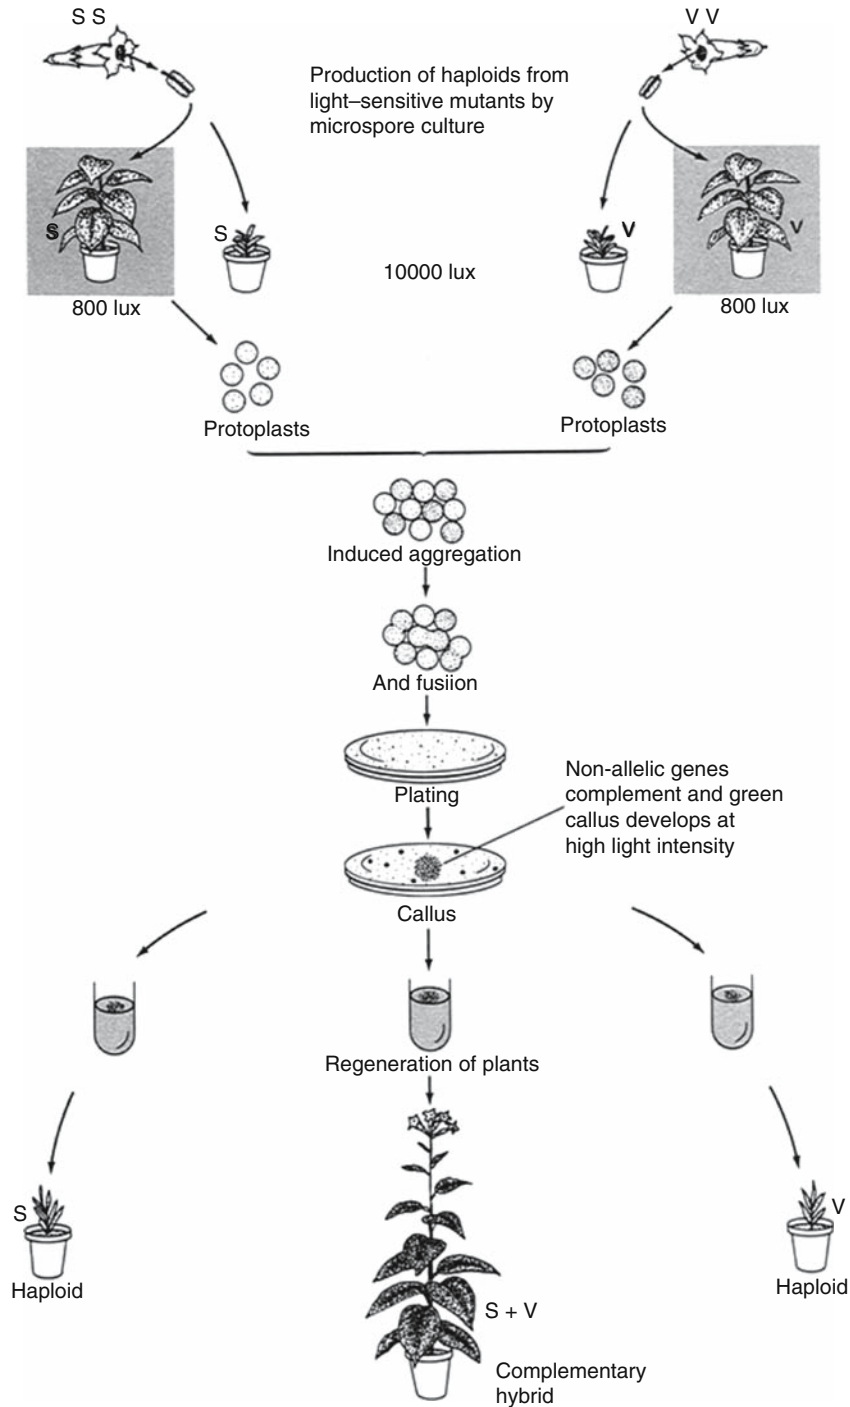

Figure S85. Somatic-cell hybrid production between non-allelic tobacco mutants. (Redrawn by permission after Melchers G & Labib G 1974 Mol. Gen. Genet. 135:277)

Figure S86. The process of fusion of plant protoplasts. (From Fowke LC et al 1977 *Planta* 135:257)

Somatic cell fusion may also make possible the study of recombination between various mitochondria or chloroplast DNAs in cells. However, in generative hybrids, because of the uniparental (female) transmission of the organelles, such analyses are not feasible. Since plant cells generally retain totipotency in culture, the hybrid cells may be regenerated into intact organisms and can be further studied in favorable cases by the methods of classical progeny analysis.

Academic Press, San Diego, California; Rédei GP 1987 McGraw-Hill *Enc Sci Technol* 6th ed 16:628.

Somatic Cell Nuclear Transfer: After the enucleation of oocytes, the nucleus of somatic cells from the same or different animals is transferred into the oocytes and this way the donor cell or individual is cloned. This procedure was successful initially for sheep; successful procedures for mice, cows, goats, pigs, rabbits, mule, horse, rats, and dogs followed. Eventually, the oocytes with a new donated diploid nucleus is transferred into the oviduct of a female, which carries the embryo to term. Applying such techniques to human cells is restricted or prohibited in many countries. It may be permitted in the UK, Belgium, China, Singapore, South Korea and Australia under regulated conditions. In the USA, such research cannot be supported by federal funds although there are less and variable limitations for private of state-funded activities. ►nuclear transplantation, ►cloning; Lee BC et al 2005 *Nature [Lond.]* 436:641.

Somatic Crossing Over: ►mitotic crossing over

Somatic Embryogenesis: The formation of embryos either directly, or by first passing through a callus stage, from cultured adult plant cells or protoplasts. LEAFY COTYLEDON2 gene controls proteins involved in somatic embryogenesis of *Arabidopsis* (Braybrook SA et al 2006 *Proc Natl Acad Sci USA* 103:3468). In about nine animal phyla, the germline is not separated from the somatic line, therefore gametes develop from the somatic cell lineage. The situation in protists and fungi is essentially similar. A strict germline does not exist in plants either. ►embryogenesis somatic, ►embryo culture, ►apomixis, ►germline; Sata SJ et al 2000 *Methods Cell Sci* 22:299.

Somatic Hybrids: ►somatic cell fusion, ►somatic cell hybrids, ►graft hybrids, ►microfusion

Somatic Hypermutations: Somatic hypermutations generally occur in a region of one to two kilobases around the rearranged V-J regions of the immunoglobulin genes and very rarely extend into the C (constant) sections. These mutations, usually transitions, and predominantly involving guanine, are most common in the complementarity-determining region (CDR) and the events usually take place in the germinal centers. The preferred hot spots are purine-G-pyrimidine-(A/T) sequences, although not all these sequences are hot spots for mutation. The serine codons AGC and AGT can represent a hot spot but the TCA, TCC, TCG and TCT are not. The codon usage in the CDR region appears to be evolutionarily determined to secure the maximum complementarity to antigens. It is not entirely clear what determines the targeting of the hypermutations to the special area but transcriptional enhancers appear to be involved. Hypermutations are limited to the coding strand and occur in a downstream polarity. Deletions and insertions are rare. For somatic hypermutation V(D)J rearrangement is a prerequisite. Activation-induced cytidine deaminase (AID) is apparently targeted by replication protein A to the sites of V(J)D recombination and is one factor of the hypermutations of the immunoglobulin genes (Chaudhuri J et al 2004 *Nature [Lond.]* 430:992). C is deaminated to U by activation-induced deamination (AID) and either mutagenic repair of the mismatch takes place or the broken strand may lead to somatic hypermutation. Error-prone mismatch repair machinery preferentially targets non-template uracils in a way that promotes somatic hypermutation during the antibody response (Unniraman S, Schatz DG 2007 *Science* 317:1227). Somatic hypermutation, along with recombination, is the major source of antibody variation and increases the defense repertoire in mammals. The Rad6/Rad18 protein may recruit error-prone translesion polymerases to the DNA

replication of immunoglobulin G (Ig) genes (Bachl J 2006 Proc Natl Acad Sci USA 103:12081). ▶immunoglobulins, ▶CDR, ▶germinal center, ▶lymphocytes, ▶transition, ▶hot spot, ▶enhancer, ▶hypermutation, ▶mosaic, ▶cytosine deaminase, ▶UNG, ▶replication protein A, ▶translesion pathway; Harris RS et al 1999 Mutat Res 436:157; Meffre E et al 2001 J Exp Med 194:375; Papavasiliou FN, Schatz DG 2002 Cell 109:S35; Di Nola J, Neuberger MS 2002 Nature [Lond] 419:43; Honjo T et al 2005 Nature Immunol 6:655; Di Noia JM, Neuberger MS 2007 Annu Rev Biochem 76:1.

Somatic Mutation: Somatic mutation occurs in the body cells. It is undetectable if recessive, unless the individual is heterozygous. The mutation is manifested by sector formation. This procedure for testing mutability is particularly effective if multiple-marker heterozygotes are treated. It is not inherited to generative progeny unless it occurs or expands also to the germline. It has been successfully used for studies of mutation in the stamen hairs of the plant *Tradescantia*. In fungal cultures mutation in mitotic cells may appear as sectorial colonies. Somatic mutation can be studied in in vitro cell cultures. Recessive mutations are detectable for X-linked genes in hemizygous cells such as those of the male. The procedure is effective if it is directed toward loci with selectable products. If *loxP* is introduced into mammalian cells in a near centromeric region and if *neo* is inserted distal to the selectable marker, after random mutagenesis the *Cre* expressing cells—through recombination—produce homozygotes for some the mutations induced in recessive genes (Koike H et al 2002 EMBO Rep 3:433). Molecular methods (PCR) may permit the identification of the mechanisms involved such point mutations, chromosomal deletions and rearrangement. The frequency of mutation may be affected by age, and various environmental factors and these can be analyzed. ▶pseudodominance, ▶LOH, ▶bioassays in genetic toxicology, ▶*Tradescantia* stamen hairs, ▶somatic hypermutations, ▶paramutation, ▶transposable elements, ▶mosaic, ▶PCR, ▶cancer, ▶SNIP, ▶nucellus, ▶Knudson's two-mutation theory, ▶*Cre/LoxP*, ▶*neo*; Orive ME 2001 Theor Popul Biol 59(3):235; p53 mutation database: <http://www-p53.iarc.fr/>; somatic mutation in cancer: <http://www.sanger.ac.uk/genetics/CGP/cosmic/>.

Somatic Pairing: Generally, only the meiotic chromosomes pair during prophase (possibly late interphase), but in some tissues, such as the salivary glands, the chromosomes are always tightly associated. Also, mitotic association of the chromosomes is a requisite for mitotic (somatic) crossing over in a few organisms

where this phenomenon has been analyzed. (*Drosophila*, some fungi, *Arabidopsis*, etc.). ▶mitotic recombination, ▶parasexual mechanisms, ▶pairing, ▶intimate pairing, ▶polytenic chromosomes; Burgess SM et al 1999 Genes Dev 13:1627.

Somatic Recombination: ▶mitotic crossing over

Somatic Reduction: The reduction of chromosome numbers during mitosis in polyploids.

Somatic Segregation: The unequal distribution of genetic elements during mitoses. ▶mitotic crossing over, ▶somatic mutation, ▶sorting out, ▶chloroplast genetics, ▶mosaic

Somatogamy: The fusion of sexually undifferentiated fungal hypha tips. ▶fungal life cycles

Somatomedin: A second messenger-type polypeptide. In association with other binding proteins, it is involved in the stimulation of several cellular functions. ▶insulin-like growth factor, ▶pituitary dwarfness, ▶second messenger; Deng G et al 2001 J Cell Physiol 189:23.

Somatoplastic Sterility: In certain plant hybrids, the nucellus may show excessive growth, and chokes the embryo to death. The embryo can be rescued if excised early and transferred to in vitro culture media. ▶embryo culture

Somatostatin: A 14–20-amino acid long hypothalamic neuropeptide inhibits the release of several hormones (somatotropin, thyrotropin, corticotropin, glucagon, insulin, gastrin) in contrast to the growth hormone-releasing factor that stimulates the production of the growth hormone. The somatostatin gene has been mapped to human chromosome 3q28 and to mouse chromosome 16. Two somatostatin receptors SSTR1 and 2 (391 and 369 amino acids, respectively) with very substantial homology have been identified. They are sevenpass-transmembrane proteins frequently bound to G-proteins and distributed all over the body, at particularly high levels in the stomach, brain, and kidney. The somatostatin and dopamine receptors may co-oligomerize. ▶animal hormones, ▶G-proteins, ▶seven membrane proteins, ▶signal transduction, ▶GHRH, ▶dopamine, ▶Langerhans islets, ▶pancreas, ▶ovarian cancer; Patel YC 1999 Front Neuroendocrinol 20:157.

Somatotroph: The growth hormone-secreting cell in the adenohypophysis (in the anterior lobe of the pituitary of the brain).

Somatotropin: The mammalian growth hormone (GH, $M_r \approx 21500$), it can correct some dwarfisms when its level is increased; also it stimulates milk production.

Actually, there are three human growth hormones, all coded at chromosome 17q23-q24. Their mRNAs display about 90% homology and their amino acid sequences are shared as well. The placental lactogen protein is an even more effective growth hormone, also located nearby, and it is highly homologous. The human growth hormone gene is transcribed only in the pituitary, whereas the homologs are expressed in the placental tissues. Human and other somatotropin genes have been cloned. Transformation of mice with rat growth hormone genes increased body size substantially. ▶**dwarfism**, ▶**pituitary dwarfism**, ▶**stature in humans**; Yin D et al 2001 J Anim Sci 79:2336.

Somites: Somites are paired mesoderm blocks along the longitudinal axis (notochord) of an embryo that give rise to the vertebral column and other segmented structures. After migration, they may form the skeletal muscles. The development of the somites is controlled mainly by the Notch Wnt family and associated proteins. ▶**Notch**, ▶**wingless**; Pourquié O 2001 Annu Rev Cell Dev Biol 17:311; Pourquié O 2003 Science 301:328.

Somitogenesis: The differentiation of the somites. ▶**somites**

Son of Sevenless: ▶**SOS**

Sonic Hedgehog (Shh, human chromosome 7q36): A vertebrate gene that provides information in the head–tail direction for development; it is a rather general signaling protein of animal differentiation. *Shh* contributes to the specification of the notochord, brain, lung, and foregut. It is homologous to the *Drosophila hedgehog* (*hh*) gene; its receptors are *patched* (*ptc*) and *smoothed* (*smo*), signaling factor genes. A freely diffusible *Shh* is modified by cholesterol and a balance of Patched and the Hedgehog-interacting proteins (Hip) regulates it. Defects in *patched* may cause various carcinomas, medulloblastoma, and rhabdomyosarcoma. These genes have regulatory functions in oncogenic development. Patched activates apoptosis in neuroepithelia if its Sonic Hedgehog ligand is missing (Thibert C et al 2003 Science 301:843). ▶**hedgehog**, ▶**notochord**, ▶**holoprosencephaly**, ▶**GLI**, ▶**medulloblastoma**, ▶**rhabdomyosarcoma**; Villavicencio EH et al 2000 Am J Hum Genet 67:1047; Cohen MM Jr 2003 Am J Med Genet 123A:5; Ingham PW, Placzek M 2006 Nature Rev Genet 7:841.

Sonicator: An ultrasonic (≈20 kHz) equipment used for disrupting cells to extract contents.

Sonography: A method of ultrasonic prenatal analysis of possible structural and other defects in heart, kidney, bone, sex organs, umbilical chord, body

movements, and for verifying pregnancy, etc. Presumably, it entails no appreciable risk. ▶**ultrasonic**, ▶**prenatal diagnosis**, ▶**fetoscopy**

SopE: A guanyl-nucleotide-exchange factor for Rho and Rac GTPase proteins. It participates in the reorganization of the cytoskeleton and mediates bacterial entry into mammalian cells. After entry of the bacteria, SptP (GTPase-activating protein) restores the cytoskeleton. ▶**Rho**, ▶**Rac**, ▶**GTPase**, ▶**cytoskeleton**

Sordaria fimicola (n = 7): An ascomycete with linear spore octads. It has been extensively used for genetic recombination. A large number of mutants is available. In the 1940s, it was suspected that sexuality is relative in this fungus, but now it's been found that the poor maters are just weak mutants.

SORF: The short ORF generally includes not many more than 15 codons. ▶**codon**, ▶**ORF**

Sorghums: Arid, warm region crops. *S. bicolor* (and kaoliang), 2n = 2x = 20. *S. halepense* (Johnson grass) is tetraploid. Their nutritional value compared to other grain crops is lower because of the tannin content and low lysine level of the grain. The folding of its proteins (kafirin) lowers digestibility. Mutant varieties exist, however, that correct these deficiencies (see Fig. S87). (See Oria MP et al 2000 Proc Natl Acad Sci USA 97:5065; Klein PE et al 2000 Genome Res 10:789; molecular cytogenetics: Kim J-S et al 2005 Genetics 179:1963; <http://www.tigr.org/tdb/tgi/>).

Figure S87. Sorghum

Sori: ▶**sorus**

Sorrel: A light chestnut fur color of horses, determined by homozygosity for *d* gene; similar brownish color in other mammals. The sorrel plants *Rumex acetosella*, *R. scutatus* are used as tart vegetables. The sorrel tree is *Oxydendron*. ▶**Rumex**

Sorsby Syndrome: ▶**night blindness**, ▶**Stargardt disease**

Sortase: A bacterial enzyme that anchors surface proteins to the bacterial cell wall. These surface proteins promote interaction between the pathogen and the animal cell. Also, these proteins mediate

escape from the immune defense system of the animal cell. (See Muzmanian SK et al 2001 Mol Microbiol 40:1049).

Sortins: Proteins that inhibit the vacuolar sorting of small molecules. (See Zouhar J et al 2004 Proc Natl Acad Sci USA 101:9497).

Sorting: The mechanism that ensures that molecules (isozymes) are directed into the appropriate cellular compartments (cytosol, nucleus, mitochondria, chloroplasts). The sorted proteins are generally equipped with special NH₂-end signals, generated by differential transcription, and/or translation. This process is assisted by trans-acting transmembrane proteins and glycosylphosphatidylinositol-linked proteins. ▶[transit peptide](#), ▶[chloroplasts](#), ▶[mitochondria](#)

Sorting Out: In sorting-out, genetically different organelles (plastids, mitochondria) segregate into homogeneous groups of cells or during embryogenesis cells of common origin reaggregate in order to form certain cell types and/or structures (see Fig. S88).

Figure S88. When variegation is caused by a mutation in a nuclear gene all the plastids within a cell are either green or colorless (left). Mutation in the chloroplast genetic material display sorting out at the boundary of sectors, i.e., cells with both green and colorless plastids occur (mixed cells) and in a non-stochastic process cells with all colorless and all green plastids appear in later sectors (right).

The segregation of two different types, A and B, of mitochondria in a heteroplasmic cell line may be characterized by the formula of Solignac, M. et al (Mol Gen Genet 197:183): $V_n = p_0(1 - p_0)(1 - [1 - 1/N]^n)$ where V_n is the variance of p (the fraction of A within a cell) at the n th cell generation and p_0 = the fraction of A in the original cell line, N is the number of sorting out units. In *Schizosaccharomyces*, the distribution of the mitochondria is mediated by microtubules.

In humans, the frequency of mutation in mtDNA is 10 times higher than that in the nuclear DNA, yet heteroplasmy is very rare except in some diseases. Despite the fact that the number of mitochondria in mammalian cell runs to the thousands per cell, usually the replication switches to one type. The number of the founder mtDNAs has been estimated within wide ranges of 1–6 and 20–200 in cattle, and in *Drosophila* 370–740. These founders then undergo a restriction/amplification type of replication, i.e., they pass through a bottleneck and therefore heteroplasmy is very limited. ▶[ctDNA](#), ▶[plasmone mutation](#), ▶[plastid number](#), ▶[mtDNA](#), ▶[mitochondrial genetics](#), ▶[heteroplasmy](#), ▶[Romanovs](#); for mitochondrial sorting, see also Kowald A, Kirkwood TBL 1993 Mutat Res 295:93.

Sorus (plural sori): A group of sporangia, such as found on lower surface of fern leaves.

SOS (son of sevenless, human homolog at 2p22-p21): A *Drosophila* gene that functions downstream from *sevenless*, encoding a receptor tyrosine kinase (RTK) in the light signal transduction pathway. SOS is a guanine nucleotide releasing protein (GNRP/GNRF), it is also called guanine-nucleotide exchange factor, GEF, and it interacts with RTK through the protein Drk receptor kinase, a homolog of the vertebrate Grb2, and SEM-5 in *Caenorhabditis*. These proteins function in a variety of signal transduction pathways involving EGF. SOS is frequently also called a mediator protein. ▶[BOSS](#), ▶[DRK](#), ▶[Grb2](#), ▶[receptor tyrosine kinase \[RTK\]](#), ▶[rhodopsin](#), ▶[signal transduction](#), ▶[GNRP](#), ▶[daughter of sevenless](#), ▶[Noonan syndrome](#); Hall BE et al 2001 J Biol Chem 276:27629; Sondermann H et al 2004 Cell 119:393; crystal structure–function: Freedman TS et al 2006 Proc Natl Acad Sci USA 103:16692.

SOS Recruitment System (SRS): A tool in proteomics. A temperature-sensitive *cdc25–2* allele of yeast permits grows at 25 °C, but not at 36°. Normally this protein, when localized to the plasma membrane, facilitates Ras guanyl nucleotide exchange and via signal transduction events promotes cell growth. The human homolog (hSOS) is complementary for the mutant and secures growth at the otherwise non-permissive regime. The hSOS function requires protein–protein interaction that is secured by fusing a bait to the C-end of the truncated protein. The co-expressed bait and prey are targeted to the membrane. The prey is either an integral membrane protein or a soluble protein, which after myristoylation signaling attaches to the membrane, and then growth is restored. ▶[two-hybrid system](#), ▶[CDC25](#), ▶[proteomics](#); Auerbach D et al 2002 Proteomics 2:611.

SOS Repair: An error-prone repair. ►DNA repair

Sotos Syndrome: ►cerebral gigantism

Source Habitat: In a source habitat, some individuals contribute more to the future generations than do the average individuals. ►sink habitat, ►habitat

Southern Blotting: In Southern blotting, DNA fragments cut by restriction endonucleases are separated on agarose gel by electrophoresis, then transferred to membrane filters by blotting, to hybridize the pieces with radioactively (or fluorescent) labeled DNA or RNA and then identify the physical sites of restriction fragments and genes. The transfer to membranes may be achieved by capillary action of wicks and DNA is sucked through layers of filterpapers on top or by vacuum-driven devices (see Fig. S89). ►restriction enzyme, ►RFLP, ►autoradiography, ►biotinylation, ►fluorochromes, ►nucleic acid hybridization, ►membrane filters

Figure S89. Southern blot

Southern Hybridization: ►Southern blotting

South-Western Method: The simultaneous labeling of cDNA and binding proteins (transcription factors). The screening is carried out by hybridizing labeled probes of DNA to bind to polypeptides immobilized on nitrocellulose filters. ►Southern blot, ►Western blot

Soviet Genetics: The term Soviet Genetics is not meant to define a special genetics because science does not have ideological, political, or ethnic attributes and it transcends all boundaries. A sad exception is “soviet genetics,” a misnomer because it did not involve genetics at all and it collapsed before the implosion of the political system that nurtured and enforced it. Genetics in the Soviet Union had a very remarkable

and successful beginning. In 1944, L.C. Dunn, Professor of Zoology at Columbia University noted: “There are today literally hundreds of trained genetical investigators in the U.S.S.R., certainly more than in any other country outside the U.S.A.” (Science 99:2563). This outstanding research and teaching establishment was destroyed, however, in 1948 and geneticists suffered humiliation, persecution, and almost total physical annihilation for a period of over 20 years by lisenkoism. ►lysenkoism, ►Mitchurin

SOX (SRY type HMG box): Mammalian genes (~30) encoding proteins with over 60% similarity to the HMG box of SRY. The SOX9 gene is critical for the differentiation of the Sertoli cells and chondrocytes. Sox genes apparently encode transcription factors, are capable of transactivation of genes involved in gonadal differentiation, are involved in cartilage formation, and induce testis development in chromosomally XX mice (Vidal VPI et al 2001 Nature Genet 28:216). The bacterial Sox genes are involved in superoxide responses. The mammalian SOXs bind to a 5'-(A/T)(A/T)CAA(A/T)G site in the DNA and regulate the expression of the LINE-1 retrotransposons in human cells. The different SOX genes use different short DNA sequences for binding specific transcription factors. SOX3 transcription factor defects may involve X-linked mental retardation and growth hormone deficiency (Laumonnier F et al 2002 Am J Hum Genet 71:1450). Several human syndromes have mutation in Sox genes. ►SRY, ►HMG, ►campomelic dysplasia, ►Wolffian duct, ►Shah-Waardenburg syndrome, ►Hirschsprung disease, ►LINE, ►anti-Müllerian hormone, ►Sertoli cells, ►lymphedema, ►stem cells; Kamachi Y et al 2000 Trends Genet 16:182; Takash W et al 2001 Nucleic Acids Res 29:4274; Wilson M, Koopman P 2002 Curr Op Genet Dev 12:441.

Soybean: *Glycine max* (2n = 40, ~1100 Mb); the basic chromosome number may be x = 10. Some related species are tetraploid. This crop is of great economic significance because of the high oil (20–23%) and high protein content (39–40%) of the seed. ►legumes; polyploidy in the genome: Walling JG et al 2006 Genetics 172:1893; for gene index: <http://www.soybase.org>; <http://soybeangenome.siu.edu>.

sp: sp as a prefix indicates *Schizosaccharomyces pombe* (fission yeast) DNA, RNA or protein.

Sp1: A mammalian protein, a general transcription factor for many genes recognizing the DNA sequence: $\begin{matrix} \text{GGGCGG} \\ \text{CCCCGC} \end{matrix}$. Sp1 elements also protect CpG islands of housekeeping genes from methylation. Sp1 requires the general transcription factor TFIID and the complex CRSP. Sp3 and Sp4 are very similar; the

latter is expressed in the brain. ▶transcription factors inducible, ▶transcription factors, ▶CRSP, ▶DNA methylation, ▶LCR, ▶MDM2; Nicolás M et al 2001 J Biol Chem 276:22126.

Space Flight: The genetic effects of space flight are not entirely clear. The microgravity in cooperation with space radiation may have adverse stress consequences. (See White RJ, Averner M 2001 Nature [Lond] 409:1115).

Space Search: An experimental study of large-scale protein matrix for detection of interactions. ▶ORF-Eome

Spaced Dyads: Many regulatory sites include a pair of conserved trinucleotides, which are spaced by a non-conserved tract of fixed length. Genes with function(s) coordinated by a common regulatory element are expected to share upstream binding sequences. These elements contain fixed sites for a linker domain and the dimerization domain of transcription factors. Their analysis facilitates the identification of co-regulated genes. (See van Helden J et al 2000 Nucleic Acids Res 28:1808).

Spacer DNA: Non-transcribed nucleotide sequences between genes (IGS) in a cell. In the rDNA, there are spacers within (internal transcribed spacers, ITS) and between gene clusters (external transcribed spacers, ETS). These were thought of earlier as not-transcribed tracts but actually they represented very short transcripts. Animal mtDNA genes generally have very short (few bp) spacers. In fungi, mtDNA spacers are common and variable in length because of recombination and slippage during replication; they may also be mobile. Plastid genes of higher plants are organized into operons without interruptions. Insertions, deletions, and unequal recombinations determine the length of the spacers. ▶ribosomal RNA, ▶rrn; ITS2 database: <http://its2.bioapps.biozentrum.uni-wuerzburg.de/>.

Spanandric Males: Spanandric males occur rarely within hermaphroditic species and are sterile.

Spasmoneme: A rod-like thin bundle of filaments (2 nm each), forming a cytoplasmic organelle of 2–3 mm in extended form. When exposed to calcium, it contracts and serves as an engine for the movement of different structures within the cell of ciliated protozoa. ▶centrin; Maciejewski JJ et al 1999 J Eukaryot Microbiol 45(2):163.

Spasticity: Muscle tone; its increase causes lack of coordination in movement as it occurs in various diseases affecting the brain, such as stroke, spinal cord injuries, etc.

Spastic Paraplegia (Strumpell disease, SPG): A collection of paralytic diseases encoded by at least 14 loci under a variety of genetic control, recessive, dominant autosomal, and Xq28-linked. Genes responsible for the disease have been mapped to 14q (SPG3), 2p21-p22 (SPG4), 15q (SPG6), 12q13, and 8q (SPG8). Currently, 20 genes have been mapped and eight more have been identified. The common denominator of these various genes appears to be aberrant cellular transport (Crosby AH, Proukakis C 2002 Am J Hum Genet 71:1009). The most prevalent form (40–50%) is SPG4, which encodes an AAA protein, spastin, in the microtubules. Atlastin, a Golgi-localized GTPase protein interacts with spastin in axon maintenance (Evans K et al 2006 Proc Natl Acad Sci USA 103:10666). A mitochondrial ATP-dependent protease (m-AAA) defect interferes with ribosome assembly in the mitochondria and with the maturation of the L32 mitochondrial protein (Nolden M et al 2005 Cell 123:277). SPG13 is formed due to a mutation in mitochondrial Hsp60. ▶heatshock proteins, ▶Pelizaeus-Merzbacher disease, ▶Silver syndrome, ▶AAA proteins, ▶ribosomal proteins, ▶mitochondrial diseases in humans; Vazza G et al 2000 Am J Hum Genet 67:504; Svenson IK et al 2001 Am J Hum Genet 68:1077; mutations in the receptor-enhancing protein (2p22) in the mitochondria: Zuchner S et al 2006 Am J Hum Genet 79:365.

Spaying: The neutering of a female. ▶castration

SPB: ▶spindle pole body

Spearman Rank-Correlation Test (SPC): SPC determines the relations between two variables without elaborate calculations (Table S3).

The SR correlation coefficient, $r = 1 - \frac{6 \sum d^2}{n^3 - n}$, for example, $1 - \frac{6 \times 14}{7^3 - 7} = 0.75$

In case of ties, correction can be used, $T = \frac{m^3 - m}{12}$ where m stands for the number of measurements or classifications of identical values. If, for example, there are three measurements of 5, two measurements of 7, and two amounting to 8, the correction for ties among the X trait variables becomes: $\sum Tx = \frac{3^3 - 3}{12} + \frac{2^3 - 2}{12} + \frac{2^3 - 2}{12}$ and in a similar way, the correction for ties can be determined in the Y series. Now we can obtain the terms: $\sum X^2 = \frac{n^3 - n}{12} - \sum Tx$, and $\sum Y^2 = \frac{n^3 - n}{12} - \sum Ty$, and $r = \frac{\sum X^2 + \sum Y^2 - \sum d^2}{2\sqrt{\sum X^2 \sum Y^2}}$

It is a non-parametric test and can also be used for the comparison of traits that cannot be measured but can be classified subjectively (on the basis of their appearance). If the traits are quantified by measures, they are ranked according to their relative magnitude,

Table S3. Example of hypothetical data for the calculation of the Spearman Rank Correlation test

| Pairs | Trait X | Rank | Trait Y | Rank | Difference of Ranks (<i>d</i>) | <i>d</i> ² |
|-------|---------|------|---------|------|----------------------------------|--------------------------------|
| 1 | 8 | 3 | 14 | 2 | 1 | 1 |
| 2 | 10 | 5 | 20 | 7 | -2 | 4 |
| 3 | 12 | 7 | 17 | 5 | 2 | 4 |
| 4 | 9 | 4 | 15 | 3 | 1 | 1 |
| 5 | 6 | 1 | 13 | 1 | 0 | 0 |
| 6 | 11 | 6 | 18 | 6 | 0 | 0 |
| 7 | 7 | 2 | 16 | 4 | -2 | 4 |
| | | | | | Sum <i>d</i> = 0 | Sum <i>d</i> ² = 14 |

i.e., by assigning the highest rank to the largest. If an exact measurement is impractical (e.g., degree of susceptibility), they are simply ranked. In case of ties, an equal rank is assigned to both. The differences of the rank scores are squared and summed. Tables constructed for various degrees of freedom can be used to determine the probabilities. ►correlation, ►non-parametric tests, ►statistics

Specialized Transduction: In specialized transduction, the transducer temperate phage picks up a piece of the host DNA at the immediate vicinity of its established prophage site (and generally leaves behind a comparable length of its own). When this modified phage infects another bacterium, it may integrate into the host genome the gene that it picked up from the previous host. Lambda phage (λgal; meaning a defective lambda that carries *gal*) is a typical specialized transducer with preferred site near 17 min on the map next to the *gal* locus, and it is a specialized transducer of this gene. Another well-known specialized transducer phage is φ80trp that can carry the tryptophan operon (at about 27 and 1/2 min). The specialized transducer phage must be a temperate phages, which transduces (only) the special gene located at its integration site. Gene transfer in eukaryotes by transposable elements, the genetic vectors, is a process similar to prokaryotic transduction. ►transposable elements, ►transformation genetic, flowchart of specialized transduction on Figure S90, ►high-frequency lysate, ►double lyso-genic, ►helper virus, ►bacterial recombination; Morse ML 1954 Genetics 39:984.

Speciation: The process by which a new species diverges from an ancestral species. Evolutionists may distinguish conventional methods of speciation when geographic isolation and accumulated

mutations cause eventually reproductive isolation. According to the *quantum model* of speciation, the divergence begins with spatial isolation followed by the survival of a few new types of individuals that give rise to reproductively isolated new forms as mutations accumulate. *Saltational* speciation comes about by sudden major mutations. *Parapatric* (or stasipatric) speciation occurs without geographic separation and it is initiated from a relatively small number of individuals that produce divergence under continued natural selection. *Sympatric* speciation occurs within the original area of dispersal, due to the emergence of a genetic isolation mechanism or sexual selection. In *homoploid hybrid speciation*, two ancestral taxa give rise to a third by hybridization without a change of chromosome number, and it may occur in the parasitic species of animals (Schwarz D et al 2005 Nature [Lond] 436:546). Reproductive isolation required for speciation may involve hybrid sterility, hybrid inviability, or special mate preference (Ortiz-Barrientos D, Noor MAF 2005 Science 310:1467). Strong assortative mating among the hybrids, favored by the wing pattern of *Heliconius* butterflies, favors hybrid speciation (Mavárez J et al 2006 Nature [Lond] 441:868). The mechanism of speciation in plants and animals differs because in animals, in contrast to plants, behavioral traits may also lead to speciation. In plants, sterility may not necessarily hinder propagation because some species reproduce primarily by vegetative means and they can practice both autogamy and cross-pollination. Chromosomal rearrangements and the action of transposable elements may lead to hybrid sterility, sexual isolation, and eventually speciation. ►evolution, ►sibling species, ►phylogeny, ►co-speciation, ►theory of evolution, ►saltation, ►neo-Darwinism, ►neo-Lamarckism, ►species, ►fertility, ►reproductive isolation, ►Müllerian mimicry, ►hybrid zone,

Figure S90. Specialized transduction (Modified after Stent GS 1971 Molecular Genetics. WH Freeman, San Francisco)

► **introgressive hybridization**; Noor MAF, Feder JL 2006 Nature Rev Genet 7:851; plant speciation review: Rieseberg LH, Willis JH 2007 Science 317:910; comprehensive compendium of species: <http://species.wikipedia.org>.

Species: A potentially interbreeding population, which shows reproductive isolation from other species (see discussion of the definition on p 371 and ff in Dobzhansky T 1949 Genetics and the Origin of Species. Columbia University Press, New York). Horizontal transfer of genes among bacteria mediated primarily by phages or direct DNA uptake in natural environment challenge the classical concept of species (Goldenfield N, Woese C 2007 Nature [Lond] 445:369). Also, recombination in mixed populations may be a force of speciation (Fraser C et al 2007 Science 315:476). The transgenic

technology somewhat confuses the classical definition because of the possibility of exchanging genes among totally different taxonomic categories. The number of eukaryotic species is not known but about 10^6 have been described. Expectations are that between 3 to 10 fold more existing have not been discovered yet. By shotgun genome sequencing of mass collection of seawater microbes in the Sargasso Sea, 148 new bacterial phylotypes were discovered representing >1.2 million so far unknown genes (Venter JJ et al 2004 Science 304:66). ► **speciation**, ► **sibling species**, ► **phylotype**, ► **shotgun sequencing**, ► **fertility**, ► **sexual isolation**, ► **species extant**, ► **transgene**, ► **OTU**, ► **endangered species act**, ► **horizontal transmission**; identification by genome profile: Watanabe T et al 2002 Genome Biol 3(2):res.0010; description of ~270,000 species of all types of organisms: <http://www.discoverlife.org/>.

Species Extant: With the increase of agricultural, industrial, and changing land use the currently alive (A), % extinct (E), and % threatened (T) species indicate an alarming reduction of biodiversity: molluscs (A) 10^5 , (E) 0.2, (T) 0.4; crustaceans: (A) $4-10^3$, (E) 0.01, (T) 3; insects (A) 10^6 , (E) 0.005, (T) 0.07; vertebrates total (A) 4.7×10^4 , (E) 0.5, (T) 5; mammals (A) 4.5×10^3 , (E) 1, (T) 11; gymnosperms (A) 758, (E) 0.3, (T) 32; dicots (A) 1.9×10^5 , (E) 0.2, (T) 9; monocots (A) 5.2×10^4 , (E) 0.2, (T) 9. (Data from Smith FDM et al 1993 Nature [Lond] 364:494). Within these larger categories, some species are much more endangered than the figures indicate. These numbers are not exactly valid because new species are being discovered. Between 1980–90 more than 100 new mammals have been identified. The extinction percentages date from the year 1600 A. D. According to Dobson, A.P. et al 1997 (Science 275:550) in the United States of America, the number of endangered species is 503 plants, 84 molluscs, 57 arthropods, 107 fish, 43 herptiles, 72 birds, and 58 mammals. Important factors affecting the survival of the feral species is the annual increase of the human populations (1.7%), urbanization, industrial and livestock production, pollution, and natural disasters.

According to the World Conservation Union 1996 biennial report (<http://www.iucn.org/themes/ssc/index.html>), currently 5205 species are endangered and risk extinction. Actually, the number of species is still unknown and the latest estimates vary from 3.5 to 10.5 million, about a third lower than some earlier estimates. The number of species in an environment has been extrapolated on the basis of the diversity of the 16S RNA of microorganisms. A new complex type of statistical approach is expected to provide better estimates than the most commonly used extrapolation from the lognormal distributions (Hong S-H et al 2006 Proc Natl Acad Sci USA 103:117). Around the world, 595 sites are in danger of imminent extinction. Of these, 203 are within partially protected and 87 in declared protected areas; 27 sites are known to be unprotected, and 48 sites have unknown protection status. In 2005, 794 species were in imminent danger, three times as many as have gone extinct since 1500 (Ricketts TH et al 2005 Proc Natl Acad Sci USA 102:18497). ►species, ►lognormal distribution, ►conservation genetics; 2000 Nature [Lond] 405:207 ff; 2001 Proc Natl Acad Sci USA 98:5389 ff; Alroy J 2002 Proc Natl Acad Sci USA 99:3706; Pitman NCA, Jørgensen PM 2002 Science 298:989; Convention on International Trade of Endangered Species (CITES) 1973 Public law 93–205.

Species, Synthetic: Synthetic species are produced in the laboratory by crossing putative ancestors of amphidiploid forms, which are partially isolated

genetically. Doubling the chromosome number of the hybrids prevents the sterility of the offspring. The synthetic species permit a verification of the putative evolutionary path of existing polyploid species by studying the pairing behavior of chromosomes, the frequency of chiasmata, the number of univalents and multivalents formed, etc. These classical cytogenetic methods may be supplemented with nucleic acid hybridization, in situ hybridization, study of proteins, nucleic acid sequences, etc. Some of the hybrid species if they ever occurred in nature, were not maintained by natural selection (see Fig. S91). ►allopolyploids, ►Triticale, ►Raphanobrassica, ►Mycoplasma, ►synthetic virus, ►speciation, ►evolution

Figure S91. Middle: *Triticale* ($2n = 56$), Left: Wheat ($2n = 42$), Right: Rye ($2n = 14$). (Courtesy of Dr. Árpád Kiss)

S

Specific Activity: The number of molecules of a substrate (μmol) acted on by enzymes (mg protein) per time (minutes) at standard temperature (25°C). Also, it means the relative amount of radioactive molecules in a chemical preparation.

Specific Combining Ability: ►combining ability

Specific Heat: Joules or calories required to raise the temperature of 1 g substance by 1°C .

Specific Locus Mutations Assays (SLT): SLTs have been used to detect X-chromosomal mutations in hemizygous males (mouse), in autosomal heterozygotes for special fur color genes such as the Oak Ridge stock heterozygous for *a*, *b*, *p*, *c^{ch}*, *se*, *d*, *s* or the Harwell tester stock (HT) heterozygous for six loci

(*a*, *bp*, *fz*, *ln*, *pa*, *pe*), or heterozygotes for thymidine kinase or hypoxanthine-guanine phosphoribosyl-transferase genes in different mammalian cell cultures (mouse, Chinese hamster ovary cells). Mutation of the wild type allele is then immediately revealed in the first generation. Similar procedures are applicable also in plants and any other diploid systems. The animal assays are not as simple as the microbial assays, e.g., the Ames test, but they are considered to be more relevant to human studies. ► [bioassays in genetic toxicology](#), ► [mutations in human populations](#), ► [doubling dose](#); Cattanach BM 1971, p 535. In: Chemical Mutagens. Hollaender A (Ed.) Plenum, New York.

Specific Rotation (α): The degrees of the plane of polarized light rotated by an optically active compound of specific concentration at 25°C: (α) = $\frac{r\nu}{nl}$, where the r = rotation in degrees, ν = volume in cubic centimeter of the solution, l = length in centimeters of the light path.

Specificity: A measure of discrimination among compounds. In DNA sequencing, it is the correctly predicted bases divided by the sum of the correctly and incorrectly predicted bases.

Specificity of Mutagen Assays: The percentage of correct identifications by presumably “non-carcinogenic” (“non-mutagenic”) agents. ► [sensitivity](#), ► [accuracy](#), ► [predictivity](#), ► [bioassays in genetic toxicology](#)

Speckles, Intranuclear (IGCs): IGCs are storage areas for primary RNA transcript processing factors; the speckles may not be the compartments of the eukaryotic splicing, which takes place rather in association with transcription. ► [splicing](#), ► [introns](#), ► [paraspeckles](#); Eilbracht J, Schmidt-Zachmann MS 2001 Proc Natl Acad Sci USA 98:3849.

Spect: ► [tomography](#)

Spectinomycin: Spectinomycin inhibits the translocation of charged tRNA from the A site to the P site of the prokaryotic ribosome by interfering with elongation factor G (see Fig. S92).

Figure S92. Spectinomycin

Spectral Genotyping: Spectral genotyping uses molecular beacons labeled with different fluorophores.

When the probes for the wild type (green) and for the mutant with one base substitution (red) are fluorophore labeled, the homozygous wild type (green) can be distinguished from the heterozygote's DNA (displaying both green and red) and the homozygous mutant showing only the other color (red). The potential color of the fluorophores can be chosen arbitrarily. This procedure can distinguish genotypes in clinical diagnostic analyses without DNA sequencing. Electrochemical examination of conformational alterations is also detectable at very low concentrations (10 pM). ► [beacons molecular](#), ► [fluorophore](#); Kostrikis LG et al 1998 Science 279:1228; Fan C et al 2003 Proc Natl Acad Sci USA 1009134.

Spectral Karyotyping: In spectral karyotyping, the chromosomes or chromosomal segments are hybridized with probes of fluorescent dyes in a combinatorial manner. Five dyes (Cy2, Spectrum Green, Cy3, Texas Red, and Cy5) provide enough combinatorial possibilities to “paint” each chromosome with a different color or shade. Although the naked human eye cannot distinguish these different hues, by the use of optical filters, Sagnac interferometer, a CCD camera, and Fourier transformation, it was possible to discriminate the special differences in standard classification colors using a computer program. The approach permitted classification of translocations that were not identifiable by other staining techniques. The lowest limit of differentiation by this technology is 500 to 1500 kbp. The procedure is applicable to clinical laboratory testing and evolutionary analyses. (See also Schröck E et al 1996 Science 273:494; ► [chromosome painting](#), ► [FISH](#), ► [GISH](#); <http://www-ermm.cbcu.cam.ac.uk/0000199Xh.htm>).

Spectrins: Filamentous tetrameric proteins (220–240 kDa) present in the red blood cells; they may constitute 30% of the membranes. Spectrins may mediate muscle and neuron organization by facilitating the binding of other proteins. They are also involved in the formation of a network on the cytoplasmic surface in cooperation with actin, dynein, ankyrin, and *band III* protein. The β II-spectrin is the same as fodrin. Several human chromosomes encode spectrins. Spectrin defects may cause auditory and motor neuropathies. ► [ankryn](#), ► [cytoskeleton](#), ► [elliptocytosis](#), ► [spherocytosis](#), ► [poikilocytosis](#), ► [dynein](#), ► [fodrin](#), ► [glycophorin](#), ► [spinocerebellar ataxia](#); Parkinson NJ et al 2001 Nature Genet 29:61.

Spectrophotometry: Spectrophotometry estimates the quality and quantity of a substance in solution on the basis of absorption of monochromatic light passing through it.

Spectrosome: A cytoplasmic organelle anchoring the mitotic spindle, and thus defining the spatial direction

of cell division. It contains spectrins, cyclin A and other regulatory proteins.

Speech and Grammar Disorder (SPCH1): A human FOXP2 ([forkhead box P2]7q31) dominant gene (locus is more than 600 kb) is involved in the lack of coordination of face and mouth muscles (verbal dyspraxia), some cognitive impairment (low IQ), and articulation and expressive language. Heterozygosity for nonsense mutation leads to the truncated protein product affecting neurodevelopment (MacDermot KD et al 2005 Am J Hum Genet 76:1074). ▶language impairment specific, ▶stuttering, ▶human intelligence, ▶dyspraxia, ▶dyslexia, ▶autism, ▶aphasia, ▶MASA syndrome; Lai CSL et al 2000 Am J Hum Genet 67:357; Enard W et al 2002 Nature [Lond] 418:869.

Spemann's Organizer: The embryonic tissue site of signals that mediate the organization of the body. Its signaling center is at the blastopore of the gastrula and releases a variety of polypeptides controlling neural and dorsal or ventral mesodermal differentiation. ▶morphogenesis, ▶organizer, ▶gastrula, ▶blastopore; Niehrs C 2001 EMBO J 20:631; De Robertis EM et al 2000 Nature Rev Genet 1:171.

Sperm: Sperm refers to the animal seminal fluid; geneticists generally understand it as the spermatozoon or plant male generative cells. In the first meaning, the word has no plural, in the other sense both singular and plural are justified. The *Drosophila* spermatozoon far exceeds in length that of any other animal's (up to 58 mm in *D. bifurcata*, although that of *D. melanogaster* is about 1.91 mm; the human spermatozoon is about 0.0045 mm (see Fig. S93), Karr TL, Pitnick S 1996 Nature [Lond] 379:405). In a single normal human ejaculate, the number of spermatozoa is within the range of 20–40 million in the seminal fluid volume of >2 mL. The human spermatozoon count shows a decreasing tendency during the last decades of life. The cause of this appears to be the increase of environmental pollutants with hormone-like effects, such as PCB, (polychlorinated biphenyl) an industrial carcinogen and pesticide, dioxin (a solvent), phthalates (may be present in cosmetics), and bisphenols (used in manufacturing resins and fungicides).

Figure S93. Outline of a human spermatozoon

During fertilization, the animal spermatozoon is attracted to the egg by chemotactic peptides, causing changes in the voltage of the membrane and altering the concentration of cAMP, cGMP, Ca^{2+} , and the activity of K^+ ion channels. In the tail of the spermatozoa, tetrameric proteins (CatSper1) form six transmembrane calcium ion channels, which are hyperactivated during ejaculation to assure appropriate motility and fertilization (Kirichok Y et al 2006 Nature [Lond] 439:73). A sperm chemoattractant protein, a member of the cysteine-rich secretory protein (CRISP) family, allurin has been isolated (Olson JH et al 2001 Proc Natl Acad Sci USA 98:11205). The sperm contains many different RNAs and proteins (Miller D et al 2005 Trends Mol Med 11(4):156), and they have roles in fertilized oocytes. Contrary to earlier views, mammalian spermatozoa can translate proteins but use the mitochondrial ribosomes for the process. These proteins have roles, while the sperm travels through the female reproductive canal and are essential for motility and fertilization (Gur Y, Breitbart M 2006 Genes Dev 20:411). Cytoskeletal proteins of the fertilizing sperm trigger oocyte maturation and ovulation of animals. The number of pollen grains (containing two sperms) released by a plant may vary between a few hundreds to tens of millions. The male poultry reduces the sperm when mating with promiscuous females but allocate more of it in matings with new and attractive females (Pizzari T et al 2003 Nature [Lond] 426:70). ▶oocyte primary, ▶environmental mutagens, ▶fertilization, ▶polyspermic fertilization, ▶gametogenesis, ▶RPTK, ▶DDT, ▶semen, ▶seleno-protein, ▶infertility, ▶acrosomal process, ▶cryopreservation; Wassarman PM et al 2001 Nature Cell Biol 3: E59; Ren D et al 2001 Nature [Lond] 413:603; Swallow JG, Wilkinson GS 2002 Biol Rev 77:153; <http://www.med.unipi.it/agp/siti/siti.htm>.

Sperm Activation: The conversion of the spermatids into moving spermatozoa. In *Caenorhabditis*, four gene loci (*spe-8*, *-12*, *-27*, and *spe-29*) control the process.

Sperm Bank: A (human) sperm depository for the purpose of artificial insemination in case of sterility of the husband or other conditions, which may warrant their use. Thousands of sperm banks (gene banks) exist in the world, most of the deposited samples are anonymous and the genetic constitution of the donors is not known completely. Since the 1930s, HJ Muller advocated the use of the sperm banks for positive eugenics purposes. Accordingly, the donors should be selected on the basis of superior talents, mental ability, and physical constitution. This idea has not been widely accepted, however, because of moral objections and biological shortcomings. Most of the

“superior phenotypes” cannot be evaluated by generally accepted criteria, and the phenotype may not fully represent the heritability of particular traits. Since artificial insemination of domestic animals became routine, sperm banks are exploited for animal breeding programs in order to produce maximal number of progeny of high-performance males. Even for animals, this technology should be used with thorough consideration of population genetics principles in order to avoid narrowing the gene pool and inbreeding. ►[in vitro fertilization](#), ►[ART](#), ►[bioethics](#); Critser JK 1998 Hum Reprod (Suppl. 2):55; Deech R 1998 Hum Reprod 13(Suppl. 2):80.

Sperm Competition: In animals where the females may mate repeatedly during the period of receptivity, the spermatozoa of different genotypes may have selective advantage or disadvantage in fertilization. The success of a particular type of spermatozoa is influenced by a large number of seminal proteins. The accessory gland proteins appear to be more polymorphic than other proteins, yet this may not distinguish between the interpretations of rapid evolution or limited selection. ►[multipaternal litter](#), ►[sperm displacement](#), ►[certation](#), ►[accessory gland](#); Fu P et al 2001 Proc R Soc Lond B Biol Sci 268:1105; Simmons LW 2001 Sperm Competition and its Evolutionary Consequences in the Insects. Princeton University Press.

Sperm Displacement: In animals where the females practice sperm storage, depending on the genetic constitution of the sperm, one or another may interfere with the fertilization of a competing sperm already present in the spermatheca of the female. In this process, the genetic constitution of the female has also a selective role. ►[sperm storage](#), ►[sperm competition](#), ►[sperm precedence](#), ►[spermatheca](#); Gilchrist AS, Partridge L 2000 Evolution Int J Org Evolution 54:534.

S

Sperm Morphology Assays in Genetic Toxicology: Sperm morphology assays are based on the expectation that mutagens and carcinogens may interfere with normal spermiogenesis, resulting in abnormal head shape, motility, and viability of the treated or exposed sperm. This expectation is met with some agents but not with all. Thus, sperm alterations may indicate mutagenic and/or carcinogenic properties but not all mutagens/carcinogens seem to affect these sperm parameters within non-lethal doses. ►[bioassays in genetic toxicology](#); Baccetti B et al 2001 Hum Reprod 16:1365.

Sperm Precedence: In multiple copulation of a female with different males within a period of receptivity, one type of sperm (usually the last mating male's) may have selective advantage in producing offspring.

►[sperm competition](#), ►[certation](#), ►[last-male sperm precedence](#); Price CS et al 2000 Evolution Int J Org Evolution 54:2028.

Sperm Receptor: ►[fertilization](#)

Sperm Selection: ►[sex selection](#)

Sperm Storage: Insects commonly store sperm in the spermatheca for two weeks, and fertilization may follow any time within this period. This is why geneticists tend to use virgin females for controlled matings. Sperm can be stored at the temperature of liquid nitrogen (−195.8 °C) and retain its ability of fertilization. The efficiency of storage depends on seminal fluid proteins that the male transmits along with the sperm. Mouse spermatozoa can be stored by freeze-drying and the function is maintained. ►[sperm bank](#), ►[sperm competition](#), ►[sperm displacement](#), ►[sperm precedence](#); Yin HZ, Seibel MM 1999 J Reprod Med 44(2):87; Mortimer D 2000 J Androl 21:357; Corley-Smith GE, Brandhorst BP 1999 Mol Reprod Dev 53:363; Kusakaba H et al 2001 Proc Natl Acad Sci USA 98:13501.

Sperm Typing: Sperm typing permits analysis of recombination in diploids, using the recombinant gametes. The method of analysis requires the analysis of PCR-amplified gamete DNA sequences of known paternal types. This type of analysis can resolve recombination even between single base pairs. The results must be scrupulously studied because the PCR method may have inherent errors. Single sperms can be separated with the aid of fluorescence activated cell sorters. If the sperms are subjected to “primer extension preamplification” (PEP) before analysis, enough material can be obtained to carry out multipoint tests. This procedure is not practical with egg cells. ►[recombination frequency](#), ►[crossing over](#), ►[maximum likelihood applied to recombination](#), ►[polymerase chain reaction](#), ►[cell sorter](#), ►[prenatal diagnosis](#), ►[genetic screening](#); Hubert R et al 1994 Nature Genet 7:420; Shi Q et al 2001 Am J Med Genet 99:34.

Spermatheca: A storage facility of insect females, for sperm to be used at a later fertilization following an initial mating. ►[sperm precedence](#), ►[sperm competition](#), ►[sperm storage](#), ►[sperm displacement](#)

Spermatia: Male sperms produced at the tip of hyphae within the spermatogonia of rust fungi; they are comparable to the microconidia. ►[conidia](#)

Spermatid: A cell formed by the secondary spermatocyte and which differentiates into a spermatozoon. ►[spermatozoon](#), ►[sperm](#), ►[gametogenesis](#), ►[spermiogenesis](#)

Spermatocyte (primary): A diploid cell that by the first division of meiosis gives rise to the haploid secondary spermatocytes. By cell division, these cells form the spermatids, which differentiate into spermatozoa in animals. In plants, the spermatocytes function in a similar manner and thus produce the microspores, which develop into pollen grains and within them the two sperms are formed either before or after the pollen tubes begins to elongate. ►gonads, ►gametogenesis

Spermatocytoma (spermocytoma): The malignancy of the testis or of undifferentiated male gonads. ►seminoma

Spermatogenesis: ►gametogenesis, ►spermiogenesis

Spermatogonia: The primordials of the sperm cells; the secondary spermatogonia, produce the primary spermatocytes. Spermatogonial stem cells can be transformed/transfected by genetic vectors in culture. If introduced into seminiferous tubules of infertile mouse, they undergo spermatogenesis and could produce mutant offspring (Kanatsu-Shinohara M et al 2006 Proc Natl Acad Sci USA 103:8018). ►gametogenesis, ►spermatocyte; in vitro culture: Feng L-Xin et al 2002 Science 297:392; Zhao G-Q, Garbers DL 2002 Dev Cell 2:537.

Spermatophyte: Seed-bearing plant. ►cryptogamic plants

Spermatozoon: The fully developed (differentiated) male germ cell, a sperm. ►sperm, ►spermatid, ►oocyte primary, ►fertilization, see Fig. S94 of a human spermatozoon.

Figure S94. Spermatozoon

Spermidine ($C_7H_{19}N_3$, *N*-[3-aminopropyl]-1,4-butanediamine): A polyamine regulating (+ or -) the binding of proteins to DNA, condensation of DNA, controlling gene expression, etc. Spermidine synthase is encoded by human chromosome 1p36-p22 and 3p14-q21 (see Fig. S95). ►spermine

Figure S95. Spermidine

Spermine ($C_{10}H_{26}N_4$, *N,N'*-bis[3-aminopropyl]tetramethylenediamine, a polyamine): The oxidative cleavage product of spermine is spermidine. Spermine

synthase was assigned to human chromosome Xp22.1 (see Fig. S96). Its mouse homolog *Gyro* [*Gy*] is suspected in hypophosphatemia, resulting in rickets, hearing disorders, etc. ►hypophosphatemia, ►hypophosphatasia, ►rickets, ►S-adenosylmethionine decarboxylase, ►polyamine

Figure S96. Spermine

Spermiogenesis: A postmeiotic process of differentiation of mature spermatozoa. It is supposed that CREM is involved in the control of genes required for the process because CREM-deficient mouse (obtained by recombination) cannot complete the first step of spermiogenesis and late spermatids are not observed. The defective spermatids are apparently eliminated by apoptosis. Histone 1 (H1) variant H1T2 localizes to the apical chromatin domain at the apical pole and it is required for the reconstruction of chromatin and the replacement of histones by protamines during spermiogenesis (Martianov I et al 2005 Proc Natl Acad Sci USA 102:2808). More than 2000 genes seem to be expressed postmeiotically in the mouse sperm (Schultz N et al 2003 Proc Natl Acad Sci USA 100:12201). ►sperm, ►spermatozoon, ►CREM, ►apoptosis, ►gametogenesis, ►transition protein, ►protamines, ►histones, ►adenovirus; Macho B et al 2002 Science 298:2388.

Spermist: ►preformation

SPF: Cell cycle S phase promoting factor, a kinase. ►cell cycle

SPF Condition: The specific pathogen-free condition of organisms maintained in a quarantine. ►quarantine; Yanabe M et al 2001 Exp Anim 50(4):293.

Spfi-1: An ETS family transcription factor. ►ETS oncogenes

SPH: Protein-binding DNA elements. ►Simian virus 40

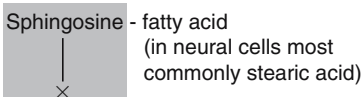

Spherocytosis, Hereditary (HS): The most common hemolytic anemia in Northern Europe. The basic defect involves both recessive and dominant mutations affecting ankyrin-1 (8p11.2) and spectrin. The β -spectrin gene was assigned to human chromosome 14q22-q23. The spectrin α -chain is responsible for elliptocytosis II (1q21). An autosomal dominant form was assigned to human chromosome 15q15. There is also an autosomal recessive type. ►ankyrin, ►spectrin, ►elliptocytosis, ►anemia, ►poikilocytosis

Spheroplast: Spherical bacterial cell after (partial) removal of the cell wall. ▶protoplast

Sphingolipid Activator Protein (SAP, Saposin): A co-factor for the physiological degradation of sphingolipids. The GM2 activators are encoded in different chromosomes and their deficiencies cause metachromatic leukodystrophy-like and Gaucher disease-like symptoms. ▶Gaucher disease, ▶metachromatic leukodystrophy; Matsuda J et al 2001 Hum Mol Genet 10:1191.

Sphingolipidoses: Hereditary diseases involving the metabolism of sphingolipids with the enzyme defects indicated in parenthesis. (See Table S4, diseases under separate entries, ▶sphingolipids).

Sphingolipids: Sphingosine-containing lipids with the following general structure and depending on the particular substitutions at X.

hydrogen (ceramide)
glucose (glucosylceramide), [neutral glycolipid]
glucose and galactose (lactosylceramide), [neutral glycolipid]
complex of sialic acid, glucose, galactose, galactose amine (ganglioside G_{M2})
phosphocholine (sphingomyelin).

If sialic acid (acetyl neuraminic acid (see Fig. S97), glycolylneuraminic acid) is removed, asialogangliosides result. Sphingolipids mediate signal transduction, calcium homeostasis and signaling, traffic of secretory vesicles, cell cycle, etc. They are the lipid moiety of glycosylphosphatidylinositol anchoring proteins. ▶sphingosine, ▶cerebrosides, ▶gangliosides, ▶sphingolipidoses, ▶Sandhoff disease, ▶ceramide; Dickson RC, Lester RL 1999 Biochim Biophys Acta

1438:305; Leipelt M et al 2001 J Biol Chem 276:33621; sphingolipid metabolic map in yeast: Alvarez-Vasquez F et al 2005 Nature [Lond] 433:425.

Figure S97. Neuraminic acid

Sphingomyelin: A phospholipid with the sphingosine amino group linked to fatty acids and the terminal OH group of sphingosine esterified to phosphorylcholine. ▶fatty acids, ▶sphingosine, ▶Niemann-Pick disease, ▶osteogenesis imperfecta

Sphingosine: A solid fatty acid-like component of membranes. The principal naturally occurring sphingosine is D(+) erythro-1,3-dihydroxy-2-amino-4-transoctadecene, CH₃(CH₂)₁₂CH=CH(OH)-CH(NH₂)-CH₂OH. In addition to the C₁₇ sphingosines shown, the molecules may have 14, 16, 18, 19, and 20 carbons. The molecules may also be branched or may contain an additional OH group. Sphingosine-1 phosphate is a rather universal signaling molecule for cell proliferation, chemotaxis, differentiation, senescence, and apoptosis. The action of sphingosine kinase is reversed by sphingosine phosphatase. Sphingosine 1-phosphate receptor mediates the egression of lymphocyte from thymus and lymphoid organs. Its activity is increased by two orders of magnitude upon blocking S1P lyase and causes

S

Spielmeyer-Sjögren-Vogt Disease: ►[ceroid](#) ►[lipo-fuscinosis](#)

Spike: An inflorescence, which is alternatively called head or ear; a typical example is the spike of wheat or some other grasses. The spikelets or flowers are sessile on opposite sides of the axis that is called rachis. Also, spike refers to short duration electrical variations along the nerve axon, a peak in electric potential.

Spike: The claw-like structures on the base plate of bacteriophages. ►[development](#)

Spikelet: A group of florets sitting on a common base in a spike (see Fig. S98). ►[spike](#)

Figure S98. Wheat spikelet

Spiked Oligos: Phosphoramidates are incorporated into deoxyribonucleotides and when these are used as primers for PCR-based mutagenesis random mutations may be selected that slow down the activity of the mutant gene products (proteins) and opens a chance to screen for extragenic suppressors that

restore better full function. ►[phosphoramidate](#), ►[PCR-based mutagenesis](#), ►[suppressor gene](#); Hermes JD et al 1989 Gene 84:143.

Spiking: Information transfer by neurons.

Spin Infection: In spin infection, adherent cells are exposed to transformation vector mix by centrifuging.

Spina Bifida: A developmental disability in various mammals, including humans, determined by autosomal dominant inheritance and reduced penetrance. The spinal column is incompletely closed and in some instances this involves no serious problem and is detectable only by X-ray examination (spina bifida occulta). The more serious case is the spina bifida aperta when the spinal cord, the membranes (meninges), spinal cord, and nerve ends are protruding (*myelomeningocele*). Hydrocephalus, incontinence, etc., frequently accompany this condition. The *meningocele* form involves only membrane extrusion and consequently it is a less severe defect. Defects in cadherins may be responsible for the anomalous differentiation. The overall frequency of these anomalies may be 0.2–0.3% in the general population. The anomaly may be the consequence of folic acid deficiency (Lucock M 2004 Br Med J 328:211). ►[neural tube defects](#), ►[prenatal diagnosis](#), ►[genetic screening](#), ►[MSAPF](#), ►[mental retardation](#), ►[hydrocephalus](#), ►[cadherins](#)

Spinach (Spinacia oleracea): A dioecious plant, $2n = 12$ (XX or XY, included). Many of the trisomics can be identified without cytological examinations. All six pairs of the chromosomes have distinct morphology.

Spinal and Bulbar Muscular Atrophy (SBMA): ►[Kennedy disease](#)

Spinal Muscular Atrophy (SMA): A degeneration of the spinal muscles; it occurs in different forms and under different genetic controls. The adult type, proximal, is autosomal dominant and may be associated with different chromosomes. The juvenile (Kugelberg-Welander syndrome) affects primarily the proximal limb muscles and frequently involves twitching. This form was assigned to human chromosome 5q11.2-q13.3. The prevalence of this type is about 1/6000 in newborns. The literature also distinguishes the Werdnig-Hoffmann disease type, however, the various juvenile forms map to the same chromosomal segment, although the expressions may differ. Deletions of this area are frequently the basis of the disease. The combined, estimated gene frequency is about 0.014. The spinal muscular dystrophy with microcephaly and mental retardation, the spinal muscular dystrophy distal (11q12-q14), SMA proximal adult type, and other variations of it appear autosomal recessive. SMA expression is positively

associated with the activity of the *survival motor neurons* controlled by the centromeric SMN2 gene (human chromosome 5q12.2-q13.3.) SMN proteins (38 kDa) are part of spliceosomal small ribonuclear simplex. The highly homologous SMN1 gene has telomeric location. The transcript of SMN2 is frequently deficient in exon 7 due to a single nucleotide substitution; otherwise it is identical with SMN1. The two proteins function in association and the truncated protein can be compensated for by higher amounts and can ameliorate the phenotype (Le TT et al 2005 Hum Mol Genet 14:865). Mutation in SMA may affect the U snRNA nuclear import system. Spinal muscular atrophy with respiratory distress (SMARD) is caused by mutation, if an immunoglobulin (IgG) binding protein (IGHMBP2) is encoded at 11q13.2-q13.4. ▶muscular atrophy, ▶Kennedy disease, ▶dystrophy, ▶atrophy, ▶lipodystrophy familial, ▶muscular dystrophy, ▶neuromuscular diseases, ▶dynein, ▶Kugelberg-Welander syndrome, ▶Silver syndrome, ▶Werdnig-Hoffmann disease, ▶URNA, ▶SMAD, ▶gemini of coiled bodies, ▶NAIP; Jablonka S et al 2001 Hum Mol Genet 10:497; Grohmann K et al 2001 Nature Genet 29:75; Feldkötter M et al 2002 Am J Hum Genet 70:358; Frugier T et al 2002 Curr Opin Genet Dev 12:294; Paushkin S et al 2002 Curr Opin Cell Biol 14:305; review of SMN1: Monani UR 2005 Neuron 48:885.

Spindle: A system of microtubules ($\approx 20\text{--}30$ nm) emanating from the poles (centrioles of the centrosomes in animals) during mitosis and meiosis, attaching to the kinetochores within the centromeres, and pulling the chromosomes toward the poles. In plants and also in some animal oocytes, there are no centrosomes and the chromosomes assume some of the centrosome functions. In yeast, the spindle forms within the nucleus. Some of the microtubules reach from one pole to the other without attaching to the kinetochore. In *Drosophila* meiosis, the spindle originates from each of the chromosomes and as the prophase progresses, a bipolar spindle emerges. This stage uses a kinesin-like protein (NCD). The arrangement of the microtubules also requires the motor protein dynein. The meiotic pole is different from the mitotic centrosomes (DMAP60, DNAP190 and γ -tubulin are apparently absent). According to a model, for the capture of microtubules and development of the spindle apparatus, the chromosomes distribute a gradient of RAN guanosine triphosphate and importin- β toward the cytoplasm, in the direction of the microtubules emanating from the centrosomes. This eventually leads to self-organization of the bipolar spindle (Caudron M et al 2005 Science 309:1373). About 200 genes determine the spindle assembly in *Drosophila* (Goshoma G et al 2007 Science 316:417).

The orientation of the spindle may be controlled in yeast by myosin V. In case of univalents, only monopolar spindle is formed. In some species, the spindle origination from the chromosome is apparently suppressed by the centrosome. In some other species, the chromosomes and the centrosomes cooperate in developing the meiotic spindle. The mitotic spindle may also need both chromosomes and the centrosomes (echinoderms) (see Fig. S99). Microtubule assembly is not an exclusive property of the kinetochores as holocentric chromosomes indicate. Anaphase and cytokinesis, however, can take place in cells after the chromosomes have been removed. On the oocyte chromosomes of several species, surface proteins (NOD, Xklp1) are found that stabilize prometaphase chromosomes, and in achiasmatic meiosis, substitute for the chiasmata. According to recent views, the information for meiotic disjunction resides within the chromosomes and not in spindle apparatus. The kinetochore determines the transition from metaphase to anaphase. The spindle checkpoint ensures the fidelity of chromosome segregation by preventing cell-cycle progression until all the chromosomes make proper bipolar attachments to the mitotic spindle and are subjected to tension. Some experiments indicate that the checkpoint recognizes the lack of microtubule attachment to the kinetochore, others indicate that the checkpoint senses the absence of tension generated on the kinetochore by microtubules. Both of these alternative explanations may be true (Pinsky BA, Biggins S 2005 Trends Cell Biol 19:486). Tension of the kinetochore generates a checkpoint signal (Cdc20, fizzy, Cdc55), and it is supposed that a phosphorylated kinetochore protein attracts proteins. At least six known genes seem to be involved in kinetochore functions. The X-chromosomes in XO cases of sex determination do not involve such a pause. The cytoskeleton is also involved in the correct organization of the spindle. The mRNA export protein Rae1 is a microtubule-associated protein that binds directly to importin β .

Figure S99. Spindle with chromosomes in the middle

and in egg extract it stabilizes microtubules by RanGTP/importin. Rae 1 is located in a large RNA-containing complex and thus indicates that RNA also has a role in spindle formation (Blower MD et al 2005 Cell 121:223). In some large cells, such as oocytes, the spindle fibers are not long enough to reach and capture the centromeres. In such cases, a contractile nuclear actin network is formed that facilitates the attachment of the centromeres to the spindle fibers (Lénárt P et al 2005 Nature [Lond] 436:812). Spindle assembly requires the presence of lamin B, which is activated by RanGTP (Tsai M-Y et al 2006 Science 311:1887). ▶nucleus, ▶centromere, ▶centromere proteins, ▶chromokinesins, ▶spindle fibers, ▶cytoskeleton, ▶tubulins, ▶myosin, ▶kinetochore, ▶chromatid, ▶mitosis, ▶meiosis, ▶BTB, ▶securin, ▶NuMA, ▶dynactin, ▶kinesin, ▶Bim, ▶univalent, ▶holocentric chromosome, ▶achiasmate, ▶Swi6p, ▶microtubule, ▶PARP, ▶RMSA-1, ▶CENP, ▶Stathmin, ▶APC, ▶multipolar spindle, ▶acenaphthene, ▶Cdc2, ▶Cdc20, ▶Cdc55, ▶Mad2, ▶RAN, ▶ASAP; Sharp DJ et al 2000 Nature [Lond] 407:41; Shah JV et al 2000 Cell 103:997; Compton DA 2000 Annu Rev Biochem 69:95; Karsenti E, Vernos I 2001 Science 294:543; Musachio A, Hardwick KG 2002 Nature Rev Mol Cell Biol 3:731; Lew DJ, Burke DJ 2003 Annu Rev Genet 37:251; Kline-Smith SL, Walczak CE 2004 Mol Cell 15:317; Gadde S, Herald R 2004 Curr Biol 14:R797; orientation of the mitotic spindle: Théry M et al 2007 Nature [Lond] 447:493; Illustration by courtesy of Dr. P.C. Koller.

Spindle Fibers: Microtubules clearly visible (by appropriate techniques) during mitotic and meiotic nuclear divisions. The microtubules originate at the spindle poles, the asters in animals. Three classes of fibers emanate from the poles: the astral microtubules that radiate from the centrioles, the polar microtubules that meet at the divisional plane and appear to stabilize the spindle, and the kinetochore microtubules that are anchored at the centromere of the chromosomes and at anaphase pull them toward the opposite poles. The eukaryotic spindle fibers are made largely of tubulin. The analogous prokaryotic system is built mainly of actin filaments. ▶spindle, ▶mitosis, ▶meiosis, ▶aster, ▶centrioles, ▶centromere, ▶kinetochore, ▶centrosome, ▶tubulins, ▶Pac-Man model

Spindle Poison: Spindle poisons block the formation of spindle fibers and as a consequence polyploidy may result. ▶polyploidy, ▶colchicine, ▶acenaphthene, ▶Stathmin

Spindle Pole Body (SPB): The fungal equivalent of the centrosome. Cyclins and cyclin-dependent kinases promote and regulate their duplication. SPBs assist

in the assembly of membrane proteins in the meiotic pro-spores of yeast. Their defect results in genetic instability, aneuploidy. SPBs affect also mRNA metabolism. ▶centrosome, ▶mitochondrial genetics; Haase SB et al 2001 Nature Cell Biol 3:38; Bajgier BK et al 2001 Mol Biol Cell 12:1611; Lang BD et al 2001 Nucleic Acids Res 29:2567.

Spinobulbar Muscular Atrophy: ▶Kennedy disease

Spinocerebellar Ataxia (SCA): Autosomal dominant defects involving CAG repeats (polyglutamine) in the coding region of the ataxin genes (SCA1, SCA2, SCA3, SCA7) and causing nerve degeneration and loss of Purkinje cell and neurons in the brain. As a consequence, motor functions deteriorate. SCA5 is due to mutation in spectrin B, which destabilizes glutamate transporter EAAT4 on the surface of the plasma membrane (Ikeda Y et al 2006 Nature Genet 38:184). SCA6 affects a calcium ion channel. In a normal state, the number of repeats is 6–44, while in the diseases state it is 40–93. The ataxin gene (SCA1) encoded at 6p23 is transcribed into 792–869 amino acids, depending on the number of CAG repeats. The mouse homolog is *Math1*. Ataxin-1 binds to RNA and controls the expansion of the polyglutamine sequences. The insect transcription factors Sens and the mammalian homolog Gfi-1 interact with the AXH domain of ataxin and mediate neurodegeneration (Tsuda H et al 2005 Cell 122:633). The SCA8 involves CTG repeats. SCA10 (22q13-qter) displays ATTCT repeats in variable numbers in intron 9. SCA12 (5q31-q33) is caused by CAG repeats in the regulatory subunit of protein phosphatase PP2A. SCA13 childhood ataxia with mental retardation and delayed motor functions is encoded at 19q13.3-q13.4. The SCA13 area contains the KCNC3 voltage-gated ion channel, and its mutation leads to neurodegeneration (Waters MF et al 2006 Nature Genet 38:447). SCAN11 (spinocerebellar ataxia with axonal neuropathy, 14q31-q32) is caused by a defect in tyrosyl-DNA phosphodiesterase (TDP1), involved in normally transient single-strand DNA break and repair generated by topoisomerase function (El-Khamisy SF et al 2005 Nature [Lond] 434:108). ▶trinucleotide repeats, ▶topoisomerases, ▶spectrin, ▶GLAST, ▶GLT, ▶Huntington chorea, ▶Kennedy disease, ▶Machado-Joseph disease, ▶myotonic dystrophy, ▶ataxia, ▶migraine, ▶CACNA1A, ▶RNAi; Stevanin G et al 2000 Eur J Hum Genet 8:4; Yue S et al 2001 Hum Mol Genet 10:25; Libby RT et al 2003 Hum Mol Genet 12:41.

Spiracle: The breathing hole on the insect body.

Spiralization: A pattern of winding of molecules or chromosomes. ▶coiling

Spirochetes (Spirochaeta): Filiform bacteria (5–6 μm) that cause sex ratio distortion in *Drosophila* by the fatal effect of their toxin on the male flies. For the killing of the male flies by *Spiroplasma poulsoni*, the normal function of the *Msl* genes of *Drosophila* (involved in dosage compensation) is required (Veneti Z et al 2005 Science 307:1461). Leptospirosis, a flu-like disease with frequent hepatic hemorrhage and jaundice, is caused *Leptospira interrogans* (see Fig. S100). Its sequenced genome consists of two chromosomes of 4,322,241 and 358,943 bp and encoding 4360 and 367 proteins, respectively. Its physiological characteristics are quite different from *Treponema* or *Borrelia*. Some lower animals (e.g., *Schistosoma*) are also called spirochetes. ▶*Schistosoma*, ▶*Treponema*, ▶*Borrelia*, ▶dosage compensation, ▶killer genes, ▶segregation distorter, ▶endosymbiont, ▶symbionts hereditary; Ren S-X et al 2003 Nature [Lond] 422:888.

Figure S100. *Leptospira* bacteria. (Courtesy of CDC Rob Weyant and Janice Carr)

Spirochete (hydantocytin): A herbicidal growth regulator of *Streptomyces hygroscopicus*. ▶herbicide

Spiroplasma: ▶symbionts hereditary, ▶sex ratio, ▶spirochetes

S

Spite: An inimical action toward other individuals without benefit to the actor.

spitz (*Drosophila* chromosome 2–54): The 2–54 locus encodes the Spitz protein, a ligand of DER. ▶DER

SPK-1: A protein kinase of the MAPK family. ▶signal transduction

Spleen: An upper left abdominal, oblong (ca. 125 mm) ductless gland. At the embryonal stage, it participates in erythrocyte formation, in adults it also manufactures lymphocytes. By decomposing the erythrocytes, it provides to the liver, the hemoglobin to form bile. The red pulp contains red blood cells and macrophages, the white pulp carries the lymphocytes. It has a role in the defense mechanism of the body. It is

generally very enlarged in some lysosomal storage diseases, e.g., Gaucher's disease. ▶asplenia, ▶lysosomal storage diseases, ▶hemophilias, ▶Gaucher's disease

Splice: The resolution of a recombination intermediate (Holliday junction), resulting in an exchange of the flanking markers. ▶Holliday model, ▶introns, ▶spliceosome

Spliceosomal Intron: Spliceosomal introns utilize spliceosomes in eukaryotes for the removal of introns in contrast to the prokaryotic group I and II introns, which do so themselves. ▶introns, ▶spliceosome, ▶splicing; origins and evolution: Rodríguez-Trelles F et al 2006 Annu Rev Genet 40:47.

Spliceosome: A protein-U snRNA (there are five main uridine-rich oligonucleotides) complex required for the folding of pre-mRNA into the proper conformation for removal of introns and splicing the transcripts of exons. The spliceosome contains about 300 proteins (Rappsilber J et al 2002 Genome Res 12:1231). The majority of eukaryotic primary transcripts contain introns with 5' GU and AG 3' splice sites, and the mammalian consensus is: (A/C) AG↓GUA/GAGU. In yeast, the consensus is: (A/G)↓GUAUGU. Less than 1% of the mammalian splice junctures are GC–AG. In the excision, the spliceosome complex U1, U2, U4–U6, and U5 snRNAs and non-snRNAs work together. Initially, the U1 and U2 snRNA attaches by base pairing to the splice and to the branch sites, respectively. The U4–U6•U5 tri-snRNP complex joins in pre-splicing complexes. This is followed by snRNP–snRNP and mRNA–snRNP interactions. U6 base-pairs with U4. During spliceosome assembly, U1 and U4 are displaced and U6 pairs with the 5' splice site and with U2 snRNA. Through the coordination of a divalent metal ion (Mg^{2+}), the U6 snRNA contributes to the splicing of the RNA transcript. The 5' splice site and the branch nucleotide then move toward each other and the 2'-OH group of the latter serves as an electron donor for the first step of splicing. The excised 5'-exon and the lariat intron-3'-exon are the reaction intermediates. This first step is followed by a reaction between the electron donor nucleophile and the electron-deficient electrophile at the 3' splice junction by the 3'-OH of the freed 5'-exon, resulting in the ligation of the exons, and the removal of the intron.

A minority (0.1%) of the introns, the AT-AC introns, occurs in some animal genes such as encoding PCNA. The 5' splice site of such introns has the consensus AT↓ACCTT and their branch site is TCCTTAAC. Their splicing complex includes U11 and U12 snRNP and one or more U5 snRNP variants (Russell AG et al 2006 Nature [Lond] 443:863). The

PCNA branch site pairs with U12 and a loop of U5 aligns the exons of PCNA for ligation. U4 and U6 snRNAs are not used, but the highly divergent U4atac and U6atac take over their role. The reaction at the 5' splice site is mediated by a metalloenzyme but not at the 3' site. The spliceosome is a huge and variable complex of proteins. For the recognition of the 3' AG splice site, U2AF³⁵ (the 35K subunit of the heterodimeric [M_r 65K] U2AF⁶⁵ protein) is required in vivo, it is needed for viability and it is present in different organisms. U2AF was considered to be only an auxiliary factor (because in vitro it was not indispensable) to recognize the 5'-polypyrimidine sequences. For splicing, the U2AF protein must be in the close vicinity of the polypyrimidine tract that is recognized by its 35K subunits. The *Drosophila* protein Sex-lethal (SXL) controls dosage compensation by inhibiting splicing of the *male-specific-lethal-2* transcripts. When the large subunit of U2AF is displaced from the polypyrimidine tract—3'AG interval by SXL, the 35K subunit can mediate the removal of the intron. In the neurons the Nova proteins regulate alternative splicing. Nova binding the YCAY nucleotide sequences (Y stands for either pyrimidine) in exons blocked U1 snRNP binding and thereby exon inclusion, whereas intronic YCAY clusters promoted spliceosome assembly and exon inclusion. Thus, mapping Nova binding sites predicts mRNA regulation in neurons (Ule J et al 2006 Nature [Lond] 444:580). ▶introns, ▶exons, ▶splicing, ▶PCNA, ▶snRNA, ▶dosage compensation; Hastings ML, Krainer AR 2001 Curr Opin Cell Biol 13:302; Nagai K et al 2001 Biochem Soc Trans 29:15; Valadkhan S, Manley JL 2001 Nature [Lond] 413:701; Sträßer K, Hurt E 2001 Nature [Lond] 413:648; Nilsen TW 1998, p 279. Schellenberg M et al 2006 Proc Natl Acad Sci USA 103:1266; Xue S et al 2006 Science 312:906; spliceosome components: Stark H, Lührmann R 2006 Annu Rev Biophys Biomol Struct 35:435; supra-spliceosomes: Chen Y-IG et al 2007 Nucleic Acids Res 35:3928.

Splicing: Joining of RNA with RNA or DNA with DNA at the sites of previous cuts. Constitutive splicing indicates that the exons are spliced in the same order as they occur in the primary RNA transcript, in contrast to alternative splicing when the exons may be joined in alternative manners, thus providing mRNAs for different proteins transcribed from the same gene. The general scheme of pre-mRNA splicing is shown in Figure S101. The *Dscam* axon guidance gene of *Drosophila* has more than 38,000 alternative splice variants and dozens of different forms may be present within single cells (Neves G et al 2004 Nature Genet 36:240). About 74% of the human genes are alternatively spliced and about 15% of the human hereditary diseases are caused by mutation in the splicing mechanism (Johnson JM et al 2003 Science 302:2141).

The splicing factor family SR (named so because they are rich in serine [S] and arginine [R]), contain an RNA recognition motif (RRM/RNP) and Ψ-RRM domain Ser-Trp-Gln-Asp-Leu-Lys-Asp, separated by a Gly rich tract. The Ser-Arg domains are well phosphorylated by the serine kinase SRPK1. The 3' splice site is recognized by the U2AF⁶⁵/U2AF³⁵ heterodimer. The former binds to the polypyrimidine sequence in the RNA, whereas the latter associates with the RS domain of other RS-containing factors or the U4/U6.U5 small ribonuclear complexes at the 5' splice site. These proteins select the splice sites and are active parts of the spliceosome complex (▶spliceosome). The ASF/SF2 family recruits the U1 snRNP to the RNA transcript. SR proteins communicate also between introns across exons, and affect alternative splicing. The SR proteins are subject to regulation. Dephosphorylation of the splicing factor SRp38 represses splicing (Shinj C et al 2004 Nature [Lond] 427:553). Between the branch site and AG, there are located polypyrimidine sequences, which

Figure S101. Pre-mRNA splicing

assist with the aid of various proteins to define the 3' splice site. Inactivation of ASF/SF2 results in genetic instability due to the formation of an R loop between RNA and the non-template strand of DNA (Li X, Manley JL 2005 Cell 122:365). Some of the many relevant proteins are PTB (polypyrimidine tract-binding protein) and PSF (PTB-associated splicing factor). The splicing reaction is driven by various nucleotidetriphosphatases. Genome-wide analysis revealed 285 human (ESR) exonic splicing regulatory sequences (Goren A et al 2006 Mol Cell 22:769). Plants also have splicing factors but these are more variable than those of animals and this is the cause why animal introns are not spliced out in plants. Splicing precedes the export of the RNA to the cytoplasm and requires the association of the mRNA with the splicing factor Aly. ▶restriction enzyme, ▶exon junction complex, ▶vectors, ▶introns, ▶speckles intranuclear, ▶lariat, ▶spliceosome, ▶alternative splicing, ▶U1 RNA, ▶snRNA, ▶alternative splicing; Madhani HD, Guthrie C 1994 Annu Rev Genet 28:1; Kramer A 1996 Annu Rev Biochem 65:367; Kim N et al 2001 EMBO J 20:2062; Thanaraj TA, Clark F 2001 Nucleic Acids Res 29:2581; Luo M-J et al 2001 Nature [Lond] 413:644; Clark TA et al 2002 Science 296:907; splicing factors: Sanford JR et al 2005 Proc Natl Acad Sci USA 102:15043; splice site prediction: <http://spliceport.cs.umd.edu:2000/SplicingAnalyser.html>.

Splicing Enhancer, Exonic (ESE): The repetitive GAA sequences associated with proteins; they facilitate the joining of exons. Pre-messenger RNA, containing introns, is retained within the nucleus. Intronless mRNAs containing ESEs were found to be poorly exported from the nucleus; spliced mRNAs produced from ESE-containing pre-mRNAs were found to be efficiently exported to the cytoplasm (Taniguchi I et al 2007 Proc Natl Acad Sci USA 104:13684). ▶pre-mRNA; Fairbrother WG et al 2002 Science 297:1007.

Splicing Inhibition: Splicing inhibition may be brought about by (phosphorothioate) 2'-O-methyl-oligoribonucleotides or morpholino oligonucleotides that are resistant RNase H (see Fig. S102).

Figure S102. Morpholine

However, sometimes these analogs activate cryptic splice sites within exons. (See Wang Z et al 2004 Cell 119:831).

Splicing Junction (splice junction): Sequences at the exon-intron boundaries. They are needed for the selective export of mature mRNAs from the nucleus. In addition, they assist in RNA surveillance that leads to degradation of mRNAs with premature transcription termination. Mutations at splice junctions may cause the removal or the ordering of some exons. ▶introns, ▶exons, ▶spliceosome, ▶RNA surveillance, ▶nonsense-mediated decay; Lykke-Andersen J et al 2001 Science 293:1836.

Splicing of Proteins: Protein splicing involves post-translational excision by an endopeptidase of polypeptides and ligation the resulting carboxy- and amino-terminal sequences. Such a mechanism may occur in prokaryotes, plants, and animals. The shorter peptide can be then sliced up by a proteasome, further processed, and short pieces may be delivered with the aid of a transporter of MHC class I molecules to the cell surface where cytotoxic T lymphocytes (CTL) may destroy them. Such a mechanism can get rid of the FGF-5 fibroblast growth factor fragment responsible for renal cancer. ▶splicing, ▶inteins, ▶CTL, ▶proteasome, ▶MHC; Hanada K-i et al 2004 Nature [Lond] 427:252.

Splign: A tool for computing cDNA-to genomic or spliced alignments. (See <http://eu-transcoder.usablenet.com/tt/www.ncbi.nlm.nih.gov/sutis/splign/>; <http://www.ncbi.nlm.nih.gov/sutis/splign/splign.cgi?textpage=downloads>).

Splinkerette: A modified vectorette for PCR walking. In a PCR reaction, the free 3' end of the bottom strand flips back on itself forming a hairpin and begins elongation further along the bottom strand. The resulting double-stranded structure is stable and it is functionally removed from further reaction (see Fig. S103). (Diagram redrawn after Devon RS et al 1995 Nucleic Acids Res 23:1644). The system is well-suited for large-scale identification of mouse gene trap events (Horn C et al 2007 Nature Genet 39:933). ▶vectorette, ▶trapping promoters

Figure S103. Splinkerette

Split Gene: The split gene is discontinuous because introns are intercalated between exons; the majority of the eukaryotic genes contains introns. ▶introns, ▶exons, ▶splicing, ▶spliceosome

Split-Hybrid System: The split-hybrid system provides means for positive selection for molecules that disrupt protein-protein interactions. The genetically engineered construct is shown in Figure S104.

Figure S104. Split-hybrid method. If binding of X and Y is prevented the VP16 transactivator cannot turn on the TetR repressor and thus permitting the expression of *HIS3* gene and can be seen by the growth of the yeast cells in histidine-free medium

SPM (scanning probe microscope): SPM images biological macromolecules under a thin layer of aqueous solution. ►scanning electronmicroscopy

Spm (suppressor mutator): A transposable element system of maize of an autonomous *Spm* and a non-autonomous (originally unnamed) element. The non-autonomous element cannot insert or excise by its own power because it is defective in the transposase enzyme. This system is the same as the *En* (*Enhancer*)-*I* (*Inhibitor*) system. The non-autonomous component has also been called *dSpm* (*defective Spm*). The original name represents the fact that insertional mutations caused by the non-autonomous *dSpm* (*I*) element revert at high frequency only when *Spm* (*En*) is introduced into the genome because the latter has a functional transposase gene. The insertion does not always eliminate the function of the target gene and both a recessive mutation and the *Spm* element may be expressed. Such a case at the *A* (anthocyan) locus of maize (chromosome 3L-149) was designated as *a-m2* (*a* mutable) because of its frequent reversion to the dominant allele and displaying sectors in the presence of *Spm* (see Fig. S105). The *Spm*-dependent alleles harbor a non-autonomous (*dSpm* or *I*) insertion element that may jump out (and cause reversion), only when the functional *Spm* is introduced. The *Spm* suppressible alleles indicate the presence of a non-autonomous element that may or may not permit the expression of the gene, but the presence of the active *Spm* allows the insert's removal. The terms *Spm-w* and *Spm-s* indicate

Figure S105. The dominant alleles of maize normally form dark color but the *a^{m-1}* allele possessing the *Spm* element may display alternative states. In the absence of an inactive *Spm* any shade of solid color may appear (bottom row) but in the presence of an active *Spm* a variety of sectors are displayed (top row). (Courtesy of Barbara McClintock)

weak and strong *Spm* transposase elements, respectively. *Inactivated Spm* has been called *Spm-i*, and elements that have alternating active and inactive phases were called *cycling Spm* (*Spm-c*), whereas very stable inactive forms were named *cryptic Spm* (*Spm-cr*). In addition, a *Modifier* factor has been named that enhances the activity of *Spm*. The various forms of the *Spm* alleles were found to alter their activity with time, according to developmental stage and extraneous factors, which cause chromosome breakage (radiation, tissue culture, etc.). The term *presetting* was applied to the phenomenon, in which *Spm* determined the expression of a gene even after its removal from the genome; but this effect later may fade away. Presetting is supposed to occur during meiosis and it is attributed to methylation. Indeed, the first exon of *Spm* is rich in cytidylic residues, the most commonly methylated base in DNA. Methylation may be instrumental in the variations and the inactivation of the various *Spm* elements named. A *Regulator* element is credited with the control of the extent of methylation. Although, the various *Spm* alleles display some heritable qualities, they appear to represent labile “changes in states” of the element, except the *dSpm* or other deletional forms. Transposition of the *Spm* elements is not tied to DNA replication and the transposition favors new insertion sites within the same chromosome, although it may move to any other part of the genome. Integration of *Spm* results in a 3 bp duplication at the target site. The frequency of insertion and excision is influenced also by the base sequences flanking the target site. The *Spm* appears to be modified by the process of excision and involves various lengths of terminal deletions, but the subterminal repetitious sequences may also be involved. Deletion of the terminal repeats abolishes transposition of the element. The abilities of *Spm* to transpose and to affect gene expression are inseparable.

The *Spm* element is transcribed into a 2.4 kb RNA with 11 exons; it includes two close open reading frames. The transcript may be alternatively spliced

into four different open reading frames, called *tnpA*, *tnpB*, *tnpC* and *tnpD*, the latter being the longest.

Transcripts *tnpA* and *tnpD* are necessary for transposition. The sequences downstream from the transcription initiation site are rich in GC base pairs and are susceptible to methylation. The active *Spm* elements, located at about 0.6 kb around the transcription start site, are not methylated. The methylated elements are, however, inactive. The entire element (8.4 kb) is flanked by 13 bp inverted repeats (CACTACAAGAAAA and TTTTCTTG TAGTG). In a region 180 bp from the 5'-end and 299 bp from its 3'-end, several copies of a receptive consensus CCGACATCTTA occur. The defective elements, *dSpm* have various lengths of internal deletions covering the entire length or part of the two open reading frames. Some partially deleted elements may still function as a weak *Spm-w* element. The function of an *Spm* element is regulated by sequences within the element and the location of the transposable element within the target genes. The function of the target genes depends on when, where, and how the *Spm* element and the target gene's transcripts are spliced. ▶transposable elements, ▶hybrid dysgenesis, ▶insertional mutation, ▶*Ac-Ds*; Fedoroff N 1989, p 375. In: Mobile DNA. Berg DE, Howe MM (Eds.) Am Soc Microbiol, Washington DC.

SPN (single nucleotide polymorphism): SPN indicates single nucleotide difference between two nucleic acids. ▶SNIP

SPO: A group of sporulation mediating proteins in yeast. (See Kee K, Keeney S 2002 Genetics 160:111).

Spondylocostal Dysostosis (SD): Non-syndromal short stature and vertebral and rib defects encoded at 19q13.1-q13.3 (see Fig. S106). The defect in the homolog of *Drosophila* gene *Delta* (*Dll3*) is involved. ▶Alagille syndrome, ▶Simpson-Golabi-Behmel syndrome

Figure S106. Spondylocostal dysostosis may involve increased size abdomen and deformed vertebral column. (Modified after Turnpenny PD, Kusumi K 2004)

Spondyloepimetaphyseal Dysplasia (SEMD): The heterogeneous group of hereditary skeletal bone and

cartilage diseases involving defects in protein sulfation. A recessive type was assigned to chromosome 10q23-q24.

Spondyloepiphyseal Dysplasia (SED): The *autosomal dominant* phenotype of SED includes flattened vertebrae, short limbs and trunk, barrel-shaped chest, cleft palate, myopia (near-sightedness), muscle weakness, hernia, and mental retardation. Collagen defects are incriminated in many cases. *Autosomal recessive* forms mimic arthritis-like symptoms (arthropathy), besides the short stature. The autosomal recessive forms may not involve flat vertebrae and the defect was attributed to a deficiency of phosphoadenosine-5'-phosphosulfate and thus to undersulfated chondroitin. An *X-linked* SED (Xp22.2-p22.1) was also described. SED type diseases were located to human chromosomes 5q13-q14.1, 12q13.11-13.2, and 19p13.1. The prevalence of the X-linked form is about 2×10^{-6} . ▶achondroplasia, ▶dwarfness, ▶arthropathy-campylodactyly, ▶chondroitin sulfate, ▶collagen, ▶Schimke immuno-osseous dysplasia; Gedeon AK et al 2001 Am J Hum Genet 68:1386.

Spontaneous Generation, Current: Until Louis Pasteur (1859–61), it was assumed by many scientists that microorganisms were formed from abiotic material even during the present geological period. However, Pasteur demonstrated that the organisms found in broth and other rich nutrients grew only when the solutions were not heated to sufficiently high temperature, were maintained for a certain duration of time, and exposed to unfiltered air. His discovery has been fundamental to modern microbiology and medicine and proved that spontaneous generation is not responsible for the current variations in microbial cultures. ▶spontaneous generation unique or recurrent, ▶lysenkoism, ▶pleomorphism, ▶biogenesis; Farley J 1972 J Hist Biol 5:285, *ibid.* 95.

Spontaneous Generation, Unique or Repeated: An explanation for the abiotic origin of life. It is assumed that after the earth was formed, simple molecules, such as water, carbon dioxide, ammonia, and methane were first formed. Subsequently, in a reducing atmosphere or at deep oceanic vents containing reducing minerals (iron and nickel sulfides) and high temperature (300–800°C), molecular nitrogen could have been reduced to ammonia. When energy sources became available at the surface (ultraviolet light), simple organic acids (acetic acid, formic acid) arose. In the presence of ammonia, methane, hydrogen, hydrogen cyanide, and lightning energy amino acids could be formed. In following steps, nucleotides could arise. Actually, under simulated early earth conditions chemists could synthesize amino acids, polypeptides,

carbohydrates, and nucleic acids. These simple organic molecules might have aggregated into some sorts of micellae (bubbles), and after self-replicating mechanisms came about the possibility for the generation of an ancestral cell with a primitive RNA as the genetic material. It is not entirely clear when, where, how, and how many times these events took place. Life is estimated to have begun 3–4 billion years ago. It is not known whether on other planets, under similar conditions to that of the earth, living cells evolved. ▶biopoiesis, ▶exobiology, ▶spontaneous generation current, ▶evolution prebiotic, ▶origin of life, ▶abiogenesis; Lennox J 1981 J Hist Philos 19:19; Harris H 2002 Things Come to Life: Spontaneous Generation Revisited. Oxford University Press, New York.

Spontaneous Mutation: Spontaneous mutation occurs at a relatively low frequency when no known mutagenic agent is or was present in the environment of the cell or organism; the cause of the mutation is thus unknown. The spontaneous frequency of mutation in mice for seven standard loci is 6.6×10^{-6} per locus. The frequency in man is in the range of 10^{-5} to 10^{-6} , in *Drosophila* 10^{-4} to 10^{-5} , in yeast *Neurospora* 10^{-5} to 10^{-9} , in bacteria 10^{-4} to 10^{-9} , and in bacteriophages, 10^{-4} to lower to 10^{-11} range has been reported. In maize, the frequency is comparable to that in other eukaryotes. At some other loci and in other organisms, it may be substantially higher or lower. In higher eukaryotes, the frequencies appear lower than in microorganisms but this does not seem to be due to intrinsic biological differences; rather it reflects the limitations of the size of the populations, which were amenable to screening. The extent of DNA repair may have profound influence on the mutations recovered. ▶mutation rate, ▶mutation spontaneous, ▶diversity; Wloch DM et al 2001 Genetics 159:441.

Spooling: Spooling assumes that the triple- or quadruple-stranded naked DNA molecules are wound into the RecA protein filament for pairing and exchange. After the formation of heteroduplexes, the DNAs are released. ▶recombination molecular mechanism

Sporadic: Sporadic refers to the rare occurrence of an off type, which does not show a clear familial pattern, and the etiology (cause or origin) is unknown. ▶epidemiology

Sporangiophore: A sporangium-bearing branch. ▶sporangium

Sporangium (plural sporangia): The spore-producing and -containing structure in lower organisms (fungi, protozoa) (see Fig. S107).

Figure S107. Sporangiphore and sporangium

Spore: A reproductive cell; generally the product of the eukaryotic *meiosis*, or it may arise *mitotically* as fungal conidiospores (conidia). The *bacterial spores* are metabolically dormant cells, surrounded by a heavy wall for protection under very unfavorable conditions.

Spore Mother Cell: ▶sporocyte

Sporidium: The “sexual” spore of basidiomycetes fungi. ▶basidium

Sporocyte: A diploid cell that produces haploid spores as a result of *meiosis*. ▶gametogenesis

Sporogenesis: The mechanism or process of spore formation. ▶meiosis, ▶conidia

Sporophore: The fruiting body capable of producing spores in fungi. ▶spore

Sporophyte: The generation of the plant life cycle that produces by *meiosis* the (1n) gametophytes. The common form of plants (displaying leaves and flowers, etc.) is the (2n) sporophytic generation. ▶gametophyte

Sporopollenin: Sporopollenins are mainly polymerized carotenoids forming the exine of the pollen grains, facilitating its adhesion to the stigma of the female reproductive structure of plants.

Sporozoite: The infective stage of protozoan life cycle; in malaria, they are formed within the mosquito. ▶malaria, ▶*Plasmodium*, ▶*Anopheles*

Sporulation: In bacteria, the process of formation of morphologically altered cells that can survive adverse conditions and assure the survival of the sporulating bacteria. *Bacillus subtilis* is a typical spore-forming bacterium. Within its cell, a new cell is pinched off to create the spore that can eventually develop into a new regular cell (see Fig. S108). Also, ascospore formation through *meiosis* in fungi is sporulation. In budding yeast, 334 sporulation-essential genes have been identified. ▶meiosis; Enyenihi AH, Saunders WS 2003 Genetics 163:47; Fujita M, Losick R 2003 Genes Dev 17:1166; <http://cmgm.stanford.edu/pbrown/sporulation/>.

Figure S108. Sporulation

Spot Test: A variation of the mutagen/carcinogen bioassays when the compound to be tested by bacterial reversions is added to the surface as a crystal or a drop after the Petri plates have been seeded by the bacterial suspension and the S9 microsomal fraction added. If the substance to be tested is mutagenic, a ring of revertant cells should appear around the spot where it was added (see Fig. S109). This type of mutagenic assay is no longer much in use. ▶Ames test, ▶plate incorporation test, ▶reversion assays of *Salmonella*; Ames BN 1971, p 267. In: Chemical Mutagens I. Hollaender A (Ed.) Plenum, New York.

Figure S109. Reversion assay of *Salmonella* bacterium by the spot test. (Courtesy of Dr. G. Ficsor)

Spotting: Spotting at specific body parts is frequently found in various species (see Fig. S110). The basic colors (melanin or melanin precursors) are generally uniformly distributed at various intensities. Mutations in regulatory cis elements create novel opportunities for transcription factors for association with the mutant sequences and determine the intensity of the local deposition of the pigment. Genes in trans

Figure S110. *Drosophila* wing spotting

locations in the genome encode the transcription factors. (Gompel N et al 2005 Nature [Lond] 433:481). ▶cis-acting element, ▶transacting element, ▶piebaldism, ▶transcription factors, ▶KIT oncogene, ▶variegation

spp: The abbreviated plural of the word species.

Spreader: A simple instrument for distributing micro-organisms on the surface of agar plates (see Fig. S111).

Figure S111. Spreader

Spreading: Moving silencing proteins along the chromosome. ▶silencer

Sprekella formosissima (Amaryllidaceae): Subtropical plant, $n = \text{ca. } 60$; genome size 1.8×10^{11} bp.

spretus: *Mus spretus*, a species of mouse, commonly used for genetic analyses.

Springer: ▶copia

Spruce (*Picea* spp): Timber tree species with $2n = 2x = 24$. ▶pine, ▶douglas fir

Sprue: A tropical intestinal disease, apparently due to infection(s).

SP-Score: ▶MP-score

SPT: A suppressor of transposition (e.g., of a Ty element) and a regulator in SAGA function in yeast. The *Drosophila* homologs are *Dspt4* and *Dspt6*. This family of genes encodes histones H2A and H2B and TATA-binding proteins. There is evidence for their regulation of transcription, replication, recombination, and some developmental processes. ▶SAGA, ▶histones, ▶transcription, ▶TBP; Yamaguchi Y et al 2001 J Biochem 129:185.

Spt Proteins: Spt proteins are involved in the elongation of RNA transcripts on DNA. ▶RNA polymerase; Winston F 2001 Genome Biol 2(reviews):1006.

SptP: ▶SopE

Squalene: ▶prenylation

Squamous: Squamous denotes scaly, e.g., as in squamous cell carcinoma, a form of epithelial cancer. Sunscreen provides some protection against it. C57BL/6 strain of mice is resistant to skin squamous carcinomas (SCCs) induced by an activated Ras oncogene, whereas FVB/N mice are highly susceptible. Susceptibility is under

the control of a carboxy-terminal polymorphism in the mouse *Ptch* gene. F1 hybrids between C57BL/6 and FVB/N strains are resistant to Ras-induced SCCs, but resistance can be overcome either by elimination of the C57BL/6 *Ptch* allele (*Ptch*B6) or by overexpression of the FVB/N *Ptch* allele (*Ptch*FVB) in the epidermis of *K5Hras*-transgenic F1 hybrid mice. The human Patched (PTCH1, 9p22.3) gene is a classical tumor suppressor gene for basal cell carcinomas and medulloblastomas. Apparently, *Ptch* is critical for determining both basal or squamous cell lineage, and both tumor types can arise from the same target cell depending on carcinogen exposure and host genetic background (Wakabayashi Y et al 2007 Nature [Lond] 445:761). ▶[epidermolysis](#), ▶[nevroid basal cell carcinoma](#), ▶[medulloblastoma](#); Lin JY, Fisher DE 2007 Nature [Lond] 445:843.

Squash: *Cucurbita maxima* (winter squash) 2n = 24, 40; *C. pepo* (summer squash) 2n = 40; *C. moschata* (pumpkin), 2n = 24, 40, 48.

Squash Preparation: For microscopic analysis of chromosomes in soft (softened) tissues, there may be no need for sectioning but the fixed and stained material can be examined after smearing it directly on the microscope slide. In some cases, the fixation is done by gentle heating on the slide followed by adding a small drop of aceto-carmin or aceto orceine stain or even just placing the specimen into a drop of acetic stain and heating. These rapid procedures may permit an estimation of the stage of meiosis or mitosis. ▶[microscopy](#), ▶[stains](#); Belling J 1921 Am Nature 55:573.

Squelching: The suppression or silencing of adverse effects.

Squirrel: *Tamiasciurus hudsonicus streator*, 2n = 46; *Callospermophilus lateralis*, 2n = 42; *Ammodontomys*, 2n = 32; *Citellus citellus*, 2n = 40.

SR1: A cytoplasmic mutant of tobacco resistant to streptomycin. ▶[Nicotiana](#), ▶[streptomycin](#)

SR Motif: Serine/arginine-rich domains in RNA-binding proteins, involved in splicing pre-mRNA transcripts. They are required in the early steps of spliceosome assembly. One SR protein (SC35) alone is sufficient to form a committed complex with human β-globin pre-mRNA. Different single SR proteins commit different pre-mRNAs to splicing and different sets of SR proteins may determine the alternative and tissue-specific splicing within an organism. The SR proteins are regulated by phosphorylation/dephosphorylation. The ASF/SF2 SR-binding protein is required for genomic stability (Li X, Manley JL 2005 Cell 122:365). ▶[splicing](#), ▶[spliceosome](#), ▶[processing](#),

SRA (steroid-receptor RNA activator): An RNA coactivator of steroid hormone receptors. ▶[nuclear receptors](#), ▶[RNA regulatory](#); Lanz RB et al 2002 Proc Natl Acad Sci USA 99:16081.

SRB: Protein stabilizing RNA polymerase II binding to general transcription factors and it phosphorylates pol II RNA polymerase. SRBs occur in eukaryotes from yeast to humans and have the forms, SRB 2, 4, 5, 6, 7, 10, and 11. The CDK-like *SRB* genes involve mutation control and promotion/suppression of transcription by phosphorylating the carboxyl-terminal of RNA pol II. ▶[transcription factors](#), ▶[transcription complex](#), ▶[kinase](#), ▶[CDK](#), ▶[RNA polymerase holoenzyme](#), ▶[open promoter complex](#), ▶[regulation of gene activity](#), ▶[TUP](#), ▶[mediator complex](#); Hampsey M, Reinberg D 1999 Curr Opin Genet Dev 9:132; Carlson M 1997 Annu Rev Cell Dev Biol 13:1.

SR-BI (scavenger receptor class B1): A high-density lipoprotein receptor mediating cholesterol uptake and secretion into the bile. PDZK1 protein regulates its expression and controls HDL level. ▶[high-density lipoprotein](#), ▶[cholesterol](#); Nakamura T et al 2005 Proc Natl Acad Sci USA 102:13404.

SRBC: Sheep red blood cell.

SRC: Rous sarcoma virus oncogene of chicken. Its product is a protein-tyrosine kinase, a cellular signal transducer. Its homology domains SH2 and SH3 are present in several cytoplasmic mediator and adaptor proteins in the signal transduction pathways in different organisms. These domains bind phosphotyrosine or proline-rich residues. Phosphorylation, dephosphorylation and proteolysis regulate SRC. In humans, SRC is in chromosome 20q12-q13. SRC may be involved in both RAS-dependent and RAS-independent signaling pathways and may lead through either FOS or MYC to transcription factors. This family of non-receptor kinases includes Src, Yes, Fgr, Fyn, Lck, Hck, Blk, Zap70, Tec, Csk. Cells display increased Src, Fyn and Lyn activity. The Src proteins may also have autoinhibitory function. The Cbl oncogene acting downstream of Src is responsible for bone resorption in osteoporosis. c-SRC has been implicated in various types of cancers. Src enzyme with mutation Arg-388 to alanine with about 5% enzyme activity can be rescued to about half of normal activity by the use of the tautomerism-inducing small

molecule of imidazole under in vivo conditions (Qiao Y et al 2006 Science 311:1293). ▶**oncogenes**, ▶**SH2**, ▶**SH3**, ▶**signal transduction**, ▶**Tec**, ▶**Zap-70**, ▶**Yes**, ▶**Fgr**, ▶**Fyn**, ▶**Lck**, ▶**Hck**, ▶**Blk**, ▶**Csk**, ▶**Cbl**, ▶**osteoporosis**, ▶**imidazole**, ▶**tautomeric shift**, ▶**TCR**; Schlessinger J 2000 Cell 100:293.

SRC-1 (steroid receptor coactivator-1): Enhances the stability of the transcription complex controlled by the progesteron receptor. It is actually a co-activator of histone acetyltransferase and mediates the access of the transcription complex within the nucleosome. ▶**transcription**, ▶**progesteron**, ▶**histone acetyltransferase**, ▶**N-CoR**, ▶**TGF**; Liu Z et al 2001 Proc Natl Acad Sci USA 98:12426; Auboef D et al 2002 Science 298:616.

SRE: A cis-acting enhancer element responding to serum induction: CC(AT)₆GG (CarG box) is present in all serum response factor regulated genes. ▶**MADS box**, ▶**TCF**, ▶**serum response element**, ▶**serum response factor**

SREBP (sterol regulatory element binding proteins): Hairpin shaped it is found in the membrane of the endoplasmic reticulum (ER). The N-terminal domain is in the cytosol and acts as a basic helix-loop-helix transcription factor. The C-terminus is also in the cytosol and it is complexed with the cleavage activating protein SREBP-SCAP, which has 8 membrane-spanning regions. When the ER is low on sterols the complex is transferred to the cleavage compartment. In case of sterol overload the complex is sequestered into the ER and there is no cleavage. SREBP controls cholesterol and lipid homeostasis (Yang F et al 2006 Nature [Lond] 442:700). Cholesterol and oxysterol bind to a hexapeptide (MELADL) of the SREBP-escort protein Scap, and causes Scap to bind to Insig anchor proteins. Oxysterols bind to Insigs, causing Insigs to bind to Scap. Mutational analysis of the six transmembrane helices of Insigs reveals that the third and fourth are important for binding Insigs to oxysterols and to Scap. Thus Insigs are oxysterol-binding proteins, explaining the long-known ability of oxysterols to inhibit cholesterol synthesis in animal cells (Radhakishnan A et al 2007 Proc Natl Acad Sci USA 104:6511). S1P and S2P process SREBP. SREBP may suppress the insulin regulator IRS-2 and has a potential therapeutic role as a drug target in some diabetes (Ide T et al 2004 Nature Cell Biol 6:351; Sun L-P et al 2007 Proc Natl Acad Sci USA 104:6519). ▶**sterols**, ▶**cholesterol**, ▶**oxysterol**, ▶**statins**, ▶**Insig**, ▶**Rip**, ▶**SCAP**, ▶**lipodystrophy**, ▶**diabetes**, ▶**ATF2**; Shimano H 2001 Progr Lipid Res 40:539; Dobrosotskaya IY et al 2002 Science 296:879.

SRF (serum response factor): A transacting regulatory protein binding to SRE and regulating serum-induced gene expression. ▶**trans-acting element**, ▶**serum response element**; Kim SW et al 2001 Oncogene 20:6638.

SRK: Self-compatibility protein receptor kinase. An Srk1 kinase associated with Cdc25 phosphatase controls mitotic checkpoints (López-Avilés S et al 2005 Mol Cell 17:49). ▶**self-incompatibility**, ▶**Cdc25**, ▶**checkpoint**; Takayama S et al Nature [Lond] 413:534.

sRNA: ▶**suppressor RNA**

sRNA: ▶**RNAi**

S-RNase: A ribonuclease responsible for pollen rejection (with factor HT) in self-incompatible plants, ▶**self-incompatibility**; Luu DT et al 2001 Genetics 159:329.

SRP (signal recognition particle): An element of polypeptide transport systems through the membranes of the endoplasmic reticulum in eukaryotes and to the plasma membranes in prokaryotes. Some of the polypeptides are inserted in the endoplasmic reticulum and others are destined toward the cell membrane for secretion. The subunit (Ffh), which recognizes the signal sequence as well as the α subunit (FtsY) of its receptor (SR) are GTPases. The SRP has a variable length RNA component (4.5 S in prokaryotes and 7SL in eukaryotes). The Ffh subunit has an N domain where the signal peptide binds and the G domain of the GTPases. Adjacent to the signal-binding pocket the methionine-rich M domain forms a small globular structure, which folds into helix-turn-helix type motif for binding the RNA component. ▶**7SL RNA**, ▶**endoplasmic reticulum**, ▶**signal sequence recognition particle**, ▶**signal peptide**, ▶**Fts**; Batey RT et al 2000 Science 287:1232; Oubridge C et al 2002 Mol Cell 9:1251.

SRS2: A helicase protein; displays single-strand Dna-dependent ATPase activity. When mutant, it increases sensitivity to genotoxic agents and may cause chromosome loss. Normally, it suppresses RAD51-dependent recombination by dislodging RAD51 protein but when it is defective, it increases recombination. ▶**RAD51**, ▶**PCNA**; Krejci L et al 2003 Nature [Lond] 423:305; Veaute X et al 2003 Nature [Lond] 423:309.

SRY (sex-determining region Y, called earlier TDF [testis determining factor]): A mammalian gene in the short arm of the Y chromosome (Yp11.3) responsible for testis determination and for the development of pro-B lymphocytes. The protein (223 amino acids) is a member of the high-mobility group proteins. In mice

this HMG protein includes a large CAG trinucleotide repeat tract, which functions as a transcriptional trans-activator and it is required for male sex expression. The expression of SRY initiates the formation of the Müllerian inhibiting substance (MIS) and the synthesis of testosterone. For normal function of SRY three insulin or insulin-like receptor tyrosine kinases are required in mouse (Nef S et al 2003 Nature [Lond] 426:291). SRY contains the DNA minor groove-binding domain, the HMG box that is conserved among mammals. Mutations affecting human sex-reversal are generally within the HMG box. Sex reversal may be the result of defect in the nuclear localization signals of SRY and the N-terminal signal is not recognized by the nuclear receptor protein β -importin (Harley VR et al 2003 Proc Natl Acad Sci USA 100:7045). A human chromosome 17q24.3-q225.1-located gene SRA-1 (sex reversal autosomal) may also be controlled by SRY. Another sex-reversal gene was identified in human chromosome 9p24. In rodents, several *tda* (testis-determining autosomal) alleles exist. In the short arm of the human X-chromosome (Xp21) there is the DSS (dosage-sensitive sex reversal) locus that may be involved in sex reversal (male→female) in case of its duplication or in case the SRY alleles are weak. Deletion in the 160 kb DSS region (DAX) does not affect male development but may cause adrenal hypoplasia. Apparently the DAX gene encodes nuclear hormone receptors. DAX1 (Nr0b1) expression ceases early in testis development but persists through the development of the ovaries. There is/are the SRYIF inhibitory factor(s) involved in gonadal differentiation. The voles (rodents) *Ellobius lutescens* 2n = 17, XO constitution in males, and females and *E. tancrei* 2n = 32–54, XX in both males and females, as a normal condition do not have SRY, whereas SRY is present in other rodents as well as in other eutherian and marsupial species. The *Sry* gene is specifically expressed in the substantia nigra of the brain of rodent males in tyrosine hydroxylase-expressing neurons and it controls specific motor behavior. This condition is not the consequence of gonadal hormone action yet it contributes to the sexual differentiation of the brain (Dewing P et al 2006 Curr Biol 16:415). ▶high mobility group proteins, ▶SOX, ▶TDF, ▶Müllerian ducts, ▶ZFY, ▶animal hormones, ▶Wolffian ducts, ▶campomelic dysplasia, ▶eutherian, ▶adrenal hypoplasia, ▶Swyer syndrome, ▶trinucleotide repeat, ▶LINE; Murphy EC et al 2001 J Mol Biol 312:481; Yuan X et al 2001 J Biol Chem 276:46647.

σ^S (RpoS): Required for the expression of many growth phase and osmotically regulated prokaryotic genes.
▶ σ subunit of RNA polymerase.

SS Blood Group: ▶MN blood group

SSA (single-strand annealing): A repair mechanism apparently employed by prokaryotes and eukaryotes when one or more units of tandem repeats are eliminated by bacterial RecBCD-mediated degradation or by other nucleases (see Fig. S112). ▶DNA repair; Van Dyck E et al 2001 EMBO Rep 2:905; Paques F, Haber JE 1999 Microbiol Mol Biol Rev 63:349, Diagram redrawn after Sugawara N et al 2000 Mol Cell Biol 20:5300.

Figure S112. SSA repair

SSA: ▶Hsp70

Ssb: ▶Hsp70

SSB: A single-strand (DNA) binding protein; in yeast it is encoded by gene *RPA1*. ▶recombination molecular mechanism, ▶replication protein A, ▶DNA repair (SOS repair); Reddy MS et al 2001 J Biol Chem 276:45959.

SSC: Somatic stem cell. ▶ESC, ▶stem cell

SSC: 1 × SSC is a solution of 0.15 M NaCl + 0.015 M sodium citrate, frequently used as a solvent for nucleic acids. ▶DNA extraction

Ssc: ▶Hsp70

SSCA (single-strand conformation analysis): ▶single-strand conformation polymorphism

SSCP: ▶single-strand conformation polymorphism

ssDNA: A single-strand DNA.

SSE: same as HSP, ▶HSP

SSEA (stage-specific embryonic antigen): Can be used as surface markers for undifferentiated embryonic stem cells.

Ssh: ▶Hsp70

Ssi: ▶Hsp70

SSI-1 (STAT-induced STAT inhibitor): ►STAT

SSLP: ►simple sequence length polymorphism

SSM (slipped-strand mispairing): ►unequal crossing over

SSN6: The yeast factor abolishing glucose repression of SUC2 invertase and regulator of nucleosome positioning in the chromatin. Other *SSN* genes are components of the RNA polymerase II complex and are negative regulators of transcription. ►SUC2, ►SNF, ►catabolite repression; Li B, Reese JJ 2001 J Biol Chem 276:33788.

SSNC (second-site non-complementation): Two heterozygous recessive mutations at different chromosomal sites exhibit mutant phenotype by some sort of interaction in contrast to expectation that non-allelic recessive mutations would be complementary. ►cis-trans test, ►allelic complementation; Halsell SR, Kiehart DP 1998 Genetics 148:1845.

SSPA (significant segment pair alignment): Each sequence is used to align with a standard other sequences. It accommodates indels and other gaps. The information obtained can be used for searches for similarities in databases. ►indel, ►BLOSUM, ►ITERALIGN; Brocchieri L, Karlin S 1998 J Mol Biol 276:249.

SSR (small segment repeat or simple sequence repeat, microsatellite): These clusters of single to multiple nucleotides within the genome occurring per ~6 to ~30 to ~80 kb in plants and per ~6 kb in mammals have been used as chromosomal markers in various types of genetic studies. They may show high degree of mutability. In bacteria, only very short repeats occur (contingency loci) and they facilitate bacterial adaptation. ►microsatellite, ►phase variation; Qi X et al 2001 Biotechniques 31:358; Bacon AL et al 2001 Nucleic Acids Res 29:4405; Moxon R et al 2006 Annu Rev Genet 40:307.

SsrA (tmRNA, 10Sa RNA): ►protein repair

SSRP1 (structure-specific recognition protein): A high-mobility group protein probably targets FACT to the nucleosomes and facilitates gene transcription by RNA polymerase II. ►FACT, ►high-mobility proteins, ►transcription factors, ►nucleosome remodeling; Bruhn SL et al 1993 Nucleic Acids Res 21:1643.

SSV: A simple sequence variation in DNA.

ST-1: A single-stranded DNA phage, related to ϕ X174 and G4. ►map, ► ϕ X174 and, ►G4, Figure S113 is by courtesy of D. N. Godson.

Figure S113. St-1 single-stranded DNA phage

Stab Culture: The microbial inoculum is introduced into agar medium by a stabbing motion of the inoculation needle or loop for the purpose of propagation.

Stabilizing Selection: ►selection types

Stable RNA: Ribosomal and tRNA that persists long in the cell in comparison to mRNA that may be degraded in minutes. ►rRNA, ►tRNA, ►mRNA

Stack: Sequence Tag Alignment and Consensus Knowledgebase: <http://ziggy.sanbi.ac.za/stack/stacksearch.htm>. ►gene indexing

Stacking Gel: A porous gel on top of the SDS polyacrylamide electrophoresis running gel. It concentrates large volumes into a thin, sharp band at the beginning of the run and thus permits sharper separation of proteins. ►electrophoresis, ►SDS

STAGE (sequence tag analysis of genomic enrichment): A method similar to ChIP-chip for detecting protein factor binding regions but use extensive short sequence determination rather than genomic tiling arrays. ►ChIP, ►ChIP-chip, ►tiling, ►STAT; mapping chromosomal STAT: Bhing AA et al 2007 Genome Res 17:910.

Staggered Cuts: After a double-stranded DNA is cut, the length of the two polynucleotides is unequal.

Staggered Extension Process (StEP): A method for in vitro mutagenesis and recombination of polynucleotides. By using it, mutant proteins can be generated in vitro. The template sequences are primed, then

repeated cycles of denaturation and very short annealing and extension follows. In each cycle, the extended fragments anneal to different templates depending on complementarity, and the extension continues until full length is formed. The template switching generates recombined sequences from different parental sequences. ▶molecular evolution, ▶directed mutation, ▶RNA-peptide fusions; Zhao H et al 1998 Nature Biotechnol 16:258; Xia G et al 2002 Proc Natl Acad Sci USA 99:6597.

Stains: For light microscopic examination of chromosomal specimens aceto-carmin, aceto-orcin or Feulgen stains are commonly used. Preparation: 0.5–1 g dry carmin powder is boiled for about half an hour under reflux in 100 mL 45% acetic or propionic acid. Orcin 1.1 g is dissolved in 45 mL glacial acetic acid or propionic acid and filled up to 100 mL by H₂O. Filter and store stoppered at about 5°C. Feulgen: 1 g leuco-basic fuchsin is dissolved by pouring over 200 mL boiling H₂O, shake, cool to 50°C, filter, add 30 mL 1/N HCl, then 3 g K₂S₂O₅, allow to bleach in dark for 24 h stoppered. Decolorize by 0.5 g carbon, shake 1 min then filter and store stoppered in refrigerator. For carmin or orcin staining, fix specimens in Carnoy and stain. For Feulgen, fix in Farmer's solution for a day, rinse with water, hydrolyze at 60 °C for 4–10 min. (The duration of hydrolyzation is critical and may need adjustment for each species). Rinse with stain for 1–3 h. Tease out tissue in 45% acetic acid, remove debris, flatten by coverslip and examine. May need overstaining with carmin if Feulgen staining is poor. For histological staining a variety of other stains may be used such as haematoxylin, methylene blue, ruthenium red, malachite green, sudan black, coomassie blue, fluorochromes, etc. may be employed. ▶fixatives, ▶sectioning, ▶light microscopy, ▶C-banding, ▶G-banding, ▶Q-banding, ▶chromosome painting, ▶harlequin stain, ▶FISH, ▶fluorochromes, ▶aequorin

Stamen: The male reproductive organs of plants composed of the anther, which contains the pollen and the filament (see Fig. S114). ▶anther, ▶pollen

Figure S114. Stamen

Stamen Hair Assay: ▶*Tradescantia*

Stamina: The capacity to endure, vigor.

Staminode(s): Infertile stamen(s).

Staminate Flower: The male flower of monoecious or dioecious plants.

Stammering: A most serious form of speech defects, *stuttering*. The sufferers usually cannot talk fluently and after involuntary stops repeat syllables or entire words. The frequency of stammering is very frequent among Japanese and very unusual among American Indians. Autosomal dominant inheritance seems to be involved. Apparent linkage to chromosomes 1, 5 and 7 was detected and to chromosome 12 the linkage displayed lod scores 4.61 to 3.51 (Riaz N et al 2005 Am J Hum Genet 76:647). ▶lod score, ▶stuttering

Standard: An accepted point of reference, e.g., standard wild type. ▶control

Standard Deviation (parametric symbol σ): A measure of the variability of members of the populations $s = \sqrt{\text{variance}}$. ▶variance, ▶standard error, ▶normal deviate

Standard Error: Measures the variation of the means of various samples of a population $s\sqrt{m}$ (by some authors standard error and standard deviation are used as synonyms); standard error of proportions or fractions or frequencies is shown by the boxed formula where p = proportion or frequency and n is the population size (or number of measurements).

$$\sqrt{\frac{p(1-p)}{n}}$$

Standard Type: Generally means the wild type used as a genetic reference. ▶wild type

Standardized Fitness: ▶selection coefficient

Stanford–Binet Test: A modified Binet intelligence test. ▶Binet test, ▶human intelligence

Stanniocalcin: The protein hormone inhibiting Ca²⁺ uptake and stimulating phosphate adsorption in fishes and mammals. (See Varghese R et al 1998 Endocrinology 139:4714).

Staphylococcus aureus: A bacterium responsible for toxic shock, scarlet fever and hospital-acquired infections and various inflammations. In some strains a conjugative plasmid has been detected that harbors trimethoprim, β -lactam, aminoglycoside as well the Tn1546 transposon carrying also vancomycin resistance. The genome sequence and partial annotations of 27 bacteria phages of *S. aureus* are available (Kwan T et al 2005 Proc Natl Acad Sci USA 102:5174). ▶toxic shock syndrome, ▶aminoglycosides, ▶ β -lactamase, ▶trimethoprim, ▶vancomycin,

►**inflammasome**; Kuroda M et al 2001 Lancet 357:1225; Weigel LM et al 2003 Science 302:1569.

STAR (signal transduction and activation of RNA): Generally, a 200 amino acid protein domain associated with the cell and RNA splicing. The tripartite domain has a single RNA-binding site, a KH module of different length (2–14) and flanked by QUA1 (80) and QUA2 (30) amino acid sequences. These complexes have been detected in a wide range of eukaryotic organisms and they appear to be regulators of translation. STAR family proteins may repress *tra-2* and cause masculinization in females. ►**Sam 68**, ►**sex determination**; Stoss O et al 2001 J Biol Chem 276:8665.

STAR (signature-tagged allele replacement): May facilitate genetic analysis in cases where mutational studies are impractical due to the essentiality of the gene for viability. ►**signature of a molecule**, ►**targeting genes**; Yu Y et al 2001 Microbiology 147:431.

STAR (subtelomeric antisilencing region): An insulator type sequence that protects a gene from the action of a silencer if it lies in between the silencer and the gene. ►**silencers**, ►**insulator**

StAR (steroidogenic acute regulatory protein, 8p11.2): Enhances mitochondrial conversion of cholesterol into pregnenolone, an intermediate in steroid biosynthesis. Mutation in the coding gene results in deficiency of adrenal and gonadal steroidogenesis, and leads to congenital lipoid adrenal hyperplasia, an autosomal recessive disorder. ►**cholesterol**, ►**steroid**, ►**pregnenolone**, ►**hormones**, ►**adrenal hyperplasia**; Petrescu AD et al 2001 J Biol Chem 276:36970.

Starch: ►**amylopectin**

Starfish: *Asterias forbesi*, 2n = 36 (see Fig. S115).

Figure S115. Starfish

Stargardt Disease: A complex recessive degenerative disease of the retina evoked by environmental factors such as smoking and high cholesterol. In both, the early onset form (macular dystrophy with flecks) and the age-related macular degeneration (AMD),

mutations in the ATP-binding cassette transporter of the retina (ABCR) gene are involved. ABCR contains 51 exons in chromosome 1p13-p21. Physically the product is located in the outer segment of the retinal rods (called also rim protein). The autosomal dominant form is caused by mutation in the ELOVL4 gene, involved in fatty acid chain elongation. In mice, so affected undigested phagosomes and lipofuscin and other fluorophores accumulate and that is followed degeneration of the retinal pigment epithelium (Karan G et al 2005 Proc Natl Acad Sci USA 102:4164). In many cases, the disease is responsible for blindness. The Sorsby fundus dystrophy, an autosomal dominant disease, appears somewhat similar but it is caused by a malfunction of the tissue inhibitor metalloproteinase-3 gene (TIMP3). ►**ABC transporters**, ►**macular degeneration**, ►**eye diseases**, ►**macular dystrophy**, ►**retinal dystrophy**, ►**retinitis pigmentosa**, ►**lipofuscin**, ►**phagosome**, ►**fluorophore**

Start: ►**cell cycle**

Start Codon: AUG in RNA that specifies either formylmethionine (in prokaryotes) or methionine (in eukaryotic cells). Note that the Met codon in mitochondria varies in different organisms. In some organisms other triplets may also initiate translation. ►**genetic code**

Start Point: The position in the transcribed DNA where the first RNA nucleotide is incorporated. ►**transcription**

Stasis: An equilibrium state without change.

STATs (signal transducers and activators of transcription): Cytoplasmic proteins, which become activated by SRC (SH2, SH3) mediated phosphorylation of tyrosine at around residue 700 and serine residues at the C-terminus through the action of Jak kinases, which are receptors for cytokine signals and enzymes at the cytosolic termini. PDGF, EGF and CSF catalyze phosphorylation also. The latter process requires the action of the 42 kDa MAPK or ERK2. Stat 1 mediates reactions to microbial and viral infections. Stat4 protein is essential for interleukin-12 mediated functions such as the induction of interferon- γ , mitogenesis and T lymphocyte killing and helper T lymphocyte differentiation. Disruption of STAT 2 & 3 cause embryonic lethality. Synthetic Sta3-inhibitory peptide (corresponding of the Tyr⁷⁰⁵ phosphorylation site of immunoglobulin G) reduced embryo transplantation by 70%. Normally phosphorylation of the luminal epithelium of the uterus by LIF (leukemia inhibitory factor) is required for implantation (Catalano RD et al 2005 Proc Natl Acad Sci USA 102:8585). STAT 5A & B are required for breast development in mice, and for the stimulation of T cell proliferation. Stat5 tetramerization is associated with

leukemogenesis (Moriggi R et al 2005 Cell Metab 1:87). Stats 1, 3, 4 recognize and activate different genes by binding to the TTCC(C/G)GGAA(TTN5AA) sequences. Rac1 GTPase may regulate STAT 3 activation through phosphorylation. Stat6 prefers TTN6AA. Cooperative binding of Stats makes possible the recognition of variations at the different binding sites. The sequence-selective recognition resides in their amino terminal domains. In humans, there are at least seven STAT genes encoding proteins of 750 to 850 amino acids. The 130-amino-terminal residues bind to multiple sites in the DNA. Residues 600–700 are homologous to SH2 domains and mediate dimerization. Disruption of Stat activity leads to the loss of interferon-controlled immunity to pathogens. STAT genes can be found in mouse (m) and human (h) chromosomes: STAT1, STAT4: m 1, h 2q12-q33, STAT 3, STAT 5A & B m 11, h 12q13-q14-1, STAT 2 & 6: m 10, h 17q11.1-q22. Stat genes occur also in *Drosophila* and *Dictyostelium*.

The PIAS family of proteins includes negative regulators of STATs. Stat3 is active in many tumors, including breast cancer. It probably activates Bcl2 protein and is thus anti-apoptotic. Sta-21 protein inhibits breast cancer cells by reducing Stat3 binding to DNA (see Fig. S116) (Song H et al 2005 Proc Natl Acad Sci USA 102:4700). ▶signal transduction, ▶Jak-STAT pathway, ▶signal transduction, ▶SRC, ▶lymphocytes, ▶leptin, ▶PDGF, ▶EGF, ▶CSF, ▶SH2, ▶SH3, ▶SSI-1, ▶interferon, ▶RAC, ▶Bcl2, ▶apoptosis, ▶STAGE; Davey HW et al 1999 Am J Hum Genet 65:959; Naka T et al 1999 Trends Biol Sci 24:394; Levy DE, Darnell JE 2002 Nature Rev Mol Cell Biol 3:651; Dupuis S et al 2003 Nature Genet 33:388.

Figure S116. STA-21

Stathmin (op18): Regulates microtubule polymerization by affecting tubulins. The activity of Stathmin is controlled through phosphorylation by chromatin. Stathmin expressed in the amygdala of the brain modulates the psychological responses of innate and learned fear in mice (Shumyatsky GP et al 2005 Cell 123:697). ▶spindle; Gavet O et al 1998 J Cell Sci 111:3333; Charbaut E et al 2001 J Biol Chem 276:16146; Niethammer P et al 2004 Science 303:1862.

Stathmokinesis: Mitotic arrest. ▶spindle poison

Statins: Inhibitors of 3-hydroxy-3-methylglutaryl-coenzyme A reductase, an important enzyme of

cholesterol biosynthesis. Cholesterol-lowering drugs reduce the incidence of Alzheimer disease too. Statins are useful also for the treatment of hypertension and autoimmune diseases by inhibiting MHC class II molecules and by shifting from T_h1-type pro-inflammatory cytokines to T_h2-type cytokines. ▶cholesterol, ▶lovastatin, ▶SREBP, ▶Alzheimer disease, ▶autoimmune disease, ▶MHC, ▶T_h, ▶cytokine; Fassbender K et al 2001 Proc Natl Acad Sci USA 98:5856.

Stationary Phase: The population size is maintained without increase or decrease. At this stage the genetic material may not replicate and the mutations occurring in bacteria are expected to be due to recombination. Mutation (chromosome breakage) in the stationary phase cells of higher eukaryotes may be one of the causes of cancer. ▶growth curve; Bull HJ et al 2001 Proc Natl Acad Sci USA 98:8334.

Stationary Renewal Process: An assumption—based on a paper of R.A. Fisher (1947 Phil Trans Roy Soc B 233:55)—that crossing over is formed as a regular sequence starting from the centromere and the length between two adjacent crossovers always following the same distribution. The idea that crossing overs begin at the centromere and proceed toward the telomere turned out to be incorrect yet the stationary renewal process gained entry into several later models of recombination, interference and mapping functions. ▶mapping function; Zhao H, Speed TP 1996 Genetics 142:1369.

Statistic: An estimate of a property of an observed set of data (e.g., mean) that bears the same relation to the data as the parameter does to the population. ▶statistics

Statistics: A mathematical discipline that assists in collecting and analyzing data; guides to make conclusions and predictions based on the analysis and reveals their trustworthiness by determining probability or likelihood. Authors with inadequate training in this discipline might have incorrectly used statistical procedures in some published papers (Giles J 2006 Nature [Lond] 443:379; ▶fluctuation test). Classical genetic analyses usually require statistical methods. Statistics is used for collections of facts on demography, industrial productivity, trade, etc., such as in statistical yearbooks. Statistics cannot replace the need for sound biological data (Spence MA et al 2003 Am J Hum Genet 72:1084). *Sufficient statistics* reduces the information to that needed for the parameter of interest and avoids nuisance parameters. ▶probability, ▶Bayes' theorem, ▶likelihood, ▶maximum likelihood, ▶non-parametric tests, ▶inference statistical, ▶nuisance parameter; Robbins LG 2000 Genetics

154:13; assistance for the use of the most frequently needed statistical procedures: <http://faculty.vassar.edu/~lowry/VassarStats.html>; <http://www.ruf.rice.edu/~lane/rvls.html>.

Statistical Mechanics: Extrapolates from the microscopic structure to macroscopic features.

Statolith: Granules that are believed to sense gravity in cells. ► [gravitropism](#)

Stature in Humans: Influenced by environmental causes such as nutrition, disease, and injuries, by the use of various medications and by simple or complex genetic factors. Heritability of human height commonly exceeds 80%. Prenatal anomalies of bone length may be determined by prenatal diagnosis. QTL analysis (Hirschorn JN et al 2001 Am J Hum Genet 69:106) of Scandinavian and Canadian populations involving 2327 individuals revealed linkage of height to 6q24-q25 (lod score 3.85), 7q31.3-q36 (lod score 3.40), 12p11.2-q14 (lod score 3.35), 13q32-q33 (lod score 3.56) and 3.26 (lod score 3.17, Wiltshire S et al 2002 Am J Hum Genet 70:543). The most common types of genetically determined human dwarfism and other defects involving reduced stature are: achondroplasia, hypochondroplasia, achondrogenesis, osteochondromatosis, dyschondrosteosis, Russel-Silver syndrome, Smith-Lemli-Opitz syndrome, Opitz-Kaveggia syndrome, dwarfism, SHORT, Aarskog syndrome, Noonan syndrome, Hirschsprung disease, Turner syndrome, Trisomy, Mulibrey nanism, hairy elbows, Pygmy. ► [growth hormone](#), ► [growth retardation](#), ► [limb defects](#), ► [exostosis](#), ► [regression](#), ► [lod score QTL](#)

STC (sequence-tagged connector): ► [genome project](#)

STCH: ► [Hsp70](#)

STE (sterile): Proteins are pheromone receptors and scaffolding proteins, and coordinate and organize the signal transduction paths in budding yeast. Ste3 and Ste2 are receptors of the α and a mating type factors, respectively. Ste7 is MAPKK, Ste4 is the β subunit, Ste18 is the γ subunit of the G trimeric proteins, Ste5 is a member of the MAPK cascade, Ste11 is MAPKKK, Ste 20 is a PAK/MEKKK protein and it is required for the MAPK activation of G $\beta\gamma$. A Ste20-like protein kinase Mst regulates chromatin structure and apoptosis. Ste12 is a transcription factor. In fission yeast, the homologs *Byr* are extra-cellular signal regulated kinase homologs of MEK and ERK. (The *Ste* [*Stellate*, 1–45.7] locus of *Drosophila* encodes protein crystals in the primary oocytes). ► [signal transduction](#), ► [G proteins](#), ► [pheromones](#), ► [MAPK](#), ► [MEK](#), ► [MEKK](#), ► [MP1](#), ► [FUS3](#), ► [KSS1](#), ► [PAK](#), ► [mating type determination in yeast](#); Graves JD et al 2001 J Biol Chem

276:14909; Ura S et al 2001 Proc Natl Acad Sci USA 98:10148; Ge B et al 2002 Science 295:1291.

Steady State: In a reaction enzyme-substrate concentration and other intermediates appear constant over time but input and output are in a flow.

Steel Factor (stem cell factor): A 40–50 kDa dimeric protein produced by the bone marrow and other cells and migrates to the hematopoietic stem cells. Its receptor is a transmembrane protein tyrosine kinase. ► [cell migration](#), ► [hematopoiesis](#), ► [tyrosine kinase](#), ► [microphthalmos](#), ► [Kit oncogene](#), ► [stem cell factor](#)

Steer: An emasculated bovine male animal. ► [emasculation](#)

Steinernema carpocapsae: A nematode. ► [Caenorhabditis](#), ► [Xenorhabdus](#)

Steinert Disease (dystrophia myotonica 1, 19q13.2-q13.3): Dominantly inherited diseases affecting different tissues and it is caused by duplication of the CTG triplet in the DNA. ► [myotonic dystrophy](#)

Stele: The core cylinder of vascular tissues in plant stems and roots. ► [root](#)

Stem Cell Factor (SCF/M-CSF, 5q33.2-q33.3): Required for the normal development of B lymphocytes. The Kit oncogene product is its receptor. ► [lymphocytes](#), ► [B cells](#), ► [Kit oncogene](#), ► [M-CSF](#); Broudy VC 1997 Blood 90:1345; Smith MA et al 2001 Acta Haematol 105:143.

Stem Cells: Stem cells of animals are not terminally differentiated, can divide without limit and when they divide the daughter cells, can remain stem cells or terminally differentiate in one or more ways (Hock H, Orkin SH 2005 Nature 435:573), or they may have a restricted potential for differentiation (*transit amplifying cell*) and with time only produce differentiated cells. When human embryonic stem cells (hESC) were encapsulated in (3D HA) hyaluronic hydrogels (but not within other hydrogels or in monolayer cultures on HA), hESCs maintained their undifferentiated state, preserved their normal karyotype, and maintained their full differentiation capacity (Gerecht S et al 2007 Proc Natl Acad Sci USA 104:11298). Among the 300–500 stem cell lines (existing in 2007), 59 human embryonic stem cell lines from 17 laboratories worldwide were characterized. The lines were not identical, however, and differences in expression of several lineage markers were evident, and several imprinted genes showed similar allele-specific expression patterns, but some gene-dependent variation was observed. Some female lines expressed readily detectable levels of XIST, whereas others did not. No significant contamination of the lines with mycoplasma, bacteria

or cytopathic viruses was detected. Despite diverse genotypes and different techniques used for derivation and maintenance, all lines exhibited similar expression patterns for several markers of human embryonic stem cells (International Stem Cell Initiative 2007 Nature Biotechnol 25:803). Differentiation could be induced within the same hydrogel by simply altering soluble factors. Mammalian embryonic stem cells, derived from the inner cell mass of the blastocyst, are considered *pluripotent*, i.e., endowed with the potential to develop any type of cells under appropriate conditions. Pluripotency of embryonic stem cells is mediated by transcription factors Oct4, Sox2 and NANOG, which co-occupy substantial portion of their target genes, encoding mainly other transcription factors and by transcriptional regulatory circuits maintain the cell's self-renewal (Boyer LA et al 2005 Cell 122:947; Wang J et al 2006 Nature [Lond] 444:364). Nanog expression in mouse is upregulated in embryonic stem cells by binding brachyury (T) and STAST3 to its enhancer element. Nanog then blocks bone morphogenetic protein-induced differentiation of mesoderm by interacting with Smad1 and interfering with the recruitment of co-activators to the Smad transcriptional complexes (Suzuki A et al 2006 Proc Natl Acad Sci USA 103:10294). Under conditions of culture suitable for embryonic stem cells, adult mouse fibroblasts required Oct3/4, Sox2, c-Myc and Klf4 for the formation of pluripotent stem cells but Nanog was not necessary. These induced pluripotent stem cells (iPS) caused tumors in nude mice containing tissues from all three germ layers. When iPS was injected into blastocysts, mouse embryonic development ensued (Takahashi K, Yamanaka S 2006 Cell 126:663). Laser-assisted injection of ES cells into eight-cell-stage embryos efficiently generates viable and healthy mice that contain no more than 0.1% host cell contamination. These mice, derived from either heterozygous or homozygous mutant ES cells, can be used directly in phenotypic analyses. The mutant phenotypes in these mice are indistinguishable from those observed in mice derived by conventional breeding (Poueymirou WT et al 2007 Nature Biotechnol 25:91).

An important development in stem cell research is the simultaneous and independent discovery of new methods for the production of pluripotent stem cells from adult somatic cells. These methods apparently obviate the need for using human embryos to which moral, ethical and legal objections exist. Furthermore the technology required for harvesting and processing human eggs has several impediments. The new methods reprogram somatic cell nuclei to an undifferentiated state by the introduction of four transcription factors Oct4, Sox2, Nanog and Lin28 (Yu J et al 2007 Science 318:1917) or Oct3/4, Sox2, Klf4 and

c-Myc (Takahashi K et al 2007 Cell 131:861). In both sets of experiments the results were comparable to that obtainable by embryonic stem cells in cell morphology, proliferation, surface antigens gene expression, epigenetic status of pluripotent cell-specific genes and telomerase activity. The reprogrammed cells have the ability to differentiate into all three primary germ layers or form teratomas and appear suitable for all the uses embryonic stem cells. One cautionary note: the somatic cells (skin fibroblasts) were transformed by a retroviral vector containing a mouse viral receptor (Sic7a1). The vector integrated into more 20 sites of the human chromosomes and increased the risk of tumorigenesis by more than 20% in mice. The c-Myc reactivation might have been the major cause of the problem. c-Myc may not be absolutely necessary and other constructs can be used; the report in Science actually does not use it. The technical problems will certainly be ironed out in the future.

Identification of stem cells requires appropriate cell autonomous markers that distinguish them from other cells in a tissue. Only a few of such markers have been found and they seem to suppress translation as a means of preventing their differentiation (Siddall NA et al 2006 Proc Natl Acad Sci USA 103:8402).

It appears that in *Drosophila*, the double-stranded RNA processing enzyme (Dicer) controls stem cell development in as much as microRNAs are required for the germline stem cells to bypass the G1/S checkpoints and maintain ability for continuous cell division (Hatfield SD et al 2005 Nature [Lond] 435:974). They occur in various tissues. *Drosophila* ovarian germ cells may dedifferentiate into stem cells (Kai T, Spradling A 2004 Nature [Lond] 428:564). In *Drosophila* ovaries ISWI chromatin remodeling protein controls germline stem cell status maintenance whereas in the ovarian somatic stem cells the DOM chromatin remodeling factor is critical (Xi R, Xie T 2005 Science 310:1487). Adult mouse ovaries can rapidly generate hundreds of oocytes despite the small number of germ cells. Spermatogonial stem cells of adult mouse testis also display pluripotency in 27% and acquire embryonic stem cell properties (Guan K et al 2006 Nature [Lond] 440:1199). Bone marrow transplantation restores oocytes production in chemosterilized or ataxia telangiectasia mutated gene-deficient sterile animals. Also, oocytes carrying donor-derived genetic markers were detected after peripheral blood transplantation (Johnson J et al 2005 Cell 122:303). The conclusions of the Johnson et al 2005 paper have been questioned (Powell K 2006 Nature [Lond] 441:795, ► [oocyte primary](#)). Although some studies indicate karyotypic stability in stem cell cultures (Amit M et al 2000 Dev Biol 227:271), more recently aneuploidy (gain of human chromosomes 17q and 12) has been observed (Draper JS et al 2004

Nature Biotechnol 22:63). Spontaneous mutation rate/nucleotides in embryonic stem cell cultures after repeated passage is $\sim 10^{-9}$ and the alterations may involve also genomic copy number (45%), mtDNA sequence (22%) and promoter methylation (90%). These mutations may or may not have serious consequences depending on their selective value (Maitra A et al 2005 Nature Genet 37:1103).

Stem cells, by definition, are expected to multiply in an undifferentiated state, besides giving rise to specialized cells, in practice, after a period of time they undergo aging and decline (see Fig. S117). In mouse embryonic stem cells both X chromosomes are demethylated or have reduced methylation and this indicates that both X chromosomes are active although one is frequently lost (Zvetkova I et al 2005 Nature Genet 37:1274). A chromosome 2 (odd ratio 4.4) factor of mouse controls aging of hematopoietic stem cells. Apparently, inadequate DNA repair is responsible for the process (Geiger H et al 2005 Proc Natl Acad Sci USA 102:5102).

The gene expression profile in embryonic, neural and hematopoietic stem cells displays some overlaps yet distinct specificities are also evident (Ramalho-Santos M et al 2002 Science 298:597; Ivanova NB et al 2002 Science 298:601). More recent data indicate that embryonic stem cells obtained by fertilization or nuclear transfer are functionally equivalent (Brambrink T et al 2006 Proc Natl Acad Sci USA 103:933). The favorable environment (niche) of hematopoietic stem cells was located to the surface of the bone marrow at the surface of the cancellous (spongy) material of the trabeculae ossis (anastomosing spicules of the bones). At this location, the number of spindle-shaped, N-cadherin⁺-CD45⁻ osteoblasts positively correlates with the number of hematopoietic stem cells (Zhang J et al 2003 Nature [Lond] 425:836). Notch activation is required for the increase

of osteoblast number (Calvi LM et al 2003 Nature [Lond] 425:841). The frequency of hematopoietic and epidermal stem cells within these tissues is $\sim 1 \times 10^{-4}$ (Schneider TE et al 2003 Proc Natl Acad Sci USA 100:11412). Cryopreserved hematopoietic cord blood stem cells may remain functional after 15 years of storage (Broxmeyer HE et al 2003 Proc Natl Acad Sci USA 100:645). Umbilical cord blood is rich in hematopoietic and other stem cells are gaining increasing attention especially for HLA-mismatched recipients (Newcomb JD et al 2007 Cell Transplant 16:150). Human umbilical cord blood hematopoietic stem/progenitor cells transplanted in utero into mouse may differentiate into human hepatocyte-like cells with evidence of the expression of human hepatocyte-specific proteins as well as partially repair or protect liver damage induced by CCl₄ (Qian H et al 2006 Int J Mol Med 18:633). Pre-immune fetus develops a no injury human-rat xenograft in which the in utero transplantation of low-density mononuclear cells (MNCs) from human umbilical cord blood (hUCB) into fetal rats at 9–11 days of gestation led to the formation of human hepatocyte-like cells (hHLCs) with different cellular phenotypes (Sun Y et al 2007 Biochem Biophys Res Commun 357:1160).

Several investigators reported that the bromodeoxyuridine or other nucleoside (analog)-labeled bone marrow cells transplanted into mouse brains transformed into new neurons and supporting glial cells (e.g., Kopen GC et al 1999 Proc Natl Acad Sci USA 96:10711). These findings may be flawed (Burns TC et al 2006 Stem Cells 24:1121), however, because the original bone marrow cells so labeled may decay and other cells can pick up the label or even cell markers and the observations may be misleading (Kuan C-Y et al 2004 J Neurosci 24:10763).

Embryonic mouse stem cells differentiate into T lymphocytes in vitro if co-cultured with OP9 cells with the Notch receptors engaged by Delta-like 1 ligand. The T cells are functional in immunodeficient mice (Schmitt TM et al 2004 Nature Immunol 5:410). Also, human embryonic stem cells, transferred into human thymic tissue growing in immunodeficient mouse, resulted in the differentiation of T lymphoid cells that appeared functional by being able to express appropriate markers (Galic Z et al 2006 Proc Natl Acad Sci USA 103:11742). Adult neural stem cells may differentiate into cells of diverse germ layers with broad developmental potentials. The balance between self-renewal of stem cells and differentiation seems to be determined by the signal receptors or their phosphorylation in the neighboring cells. In the ovaries of mammals, the initial stem cells are arrested after a finite number of divisions and then enter into meiotic prophase. Functionally they resemble the meristem in plants. The *embryonic germ cells* (EG)

Figure S117. Blastocyst

have been used for transfer into mouse blastocysts and are capable to differentiate into most types of fetal tissues, including the germline.

Oocyte differentiation takes place in vitro in mouse embryonic stem cell medium in the presence of Oct4 transcription factor. Follicular structures are formed and blastocyst-like structures were observed. After 16 days, the oocytes were ready for meiosis but did not proceed beyond prophase (Hübner K et al 2003 Science 300:1251). Mouse embryonic stem cells, however, differentiated into primordial germ cells, erased methylation, characteristic for *Igf-2* and *H19* gene methylation in imprinting, and developed into haploid male gametes and were capable of—apparently normal—fertilization of eggs (Geijsen N et al 2004 Nature [Lond] 427:148). From embryonic stem cells the regeneration of viable, fertile adults, using tetraploid embryo complementation, has been reported (Eggan K, Jaenisch R 2003 Methods Enzymol 365:25).

The synthetic heterocyclic compound, SC1, permits the propagation of murine embryonic stem cells in an undifferentiated, pluripotent state under chemically defined conditions in the absence of feeder cells, serum, and leukemia inhibitory factor. Long-term SC1-expanded murine ES cells can be differentiated into cells of the three primary germ layers in vitro and can generate chimeric mice and contribute to the germ line in vivo. Biochemical and cellular experiments suggest that SC1 works through dual inhibition of RasGAP and ERK1 (Chen S et al 2006 Proc Natl Acad Sci USA 103:17266).

Sterile, hermaphrodite male mouse could produce fertile offspring when nuclear transfer cells were injected into normal, diploid blastocysts. Many of the offspring were chimeric but one was found, which transmitted genes from the sterile hermaphrodite to fertile daughters and thus overcame the problem of the “father,” which originally lacked germ cells (Wakayama S et al 2005 Proc Natl Acad Sci USA 102:29). The feasibility of culturing pluripotent (endoderm, mesoderm, ectoderm) human embryonic stem cells (ES) opens new potential for the generation of tissues (Smith AG 2001 Annu Rev Cell Dev Biol 17:435). They may be used for the purpose of transplantation and study and treat neurodegenerative diseases (Jakel RJ et al 2004 Nature Rev Genet 5:136), spinal cord injuries, liver diseases, diabetes, immunological diseases, cancer and find means for the repopulating of hematopoietic cells, etc. (Krause DS et al 2001 Cell 105:369). Human central nervous system cells grown as neurospheres survive, migrate and express differentiation markers for neurons and oligodendrocytes after long-term engraftment in mice with spinal cord injuries. Locomotor activity was also restored (Cummings BJ et al 2005 Proc Natl Acad Sci USA 102:14069).

Stem cells derived from another individual may lead to adverse immune reaction. Neural stem cells repeatedly provided protection against inflammation of the central nervous system of mouse with an immune-like mechanism (Pluchino S et al 2005 Nature 436:266). Allogeneic, hematopoietic bone marrow cell transplantation into host cells treated by ionizing radiation or other immunosuppressive techniques, however, may become permanently tolerant of the foreign stem cells. The intolerance to a third-party donor, however, is not entirely solved (Sykes M, Nikolic B 2005 Nature [Lond] 435:620).

The immunological intolerance can be prevented when blastocysts formed from donated human oocytes (preferably by less than 30 years old donors) are used into which the nucleus of potential female or male recipient's own skin cells is transferred. The blastocysts were generated by this nuclear transfer by an average of ~24% success. The immunological identity of the stem cells to that of the donor was confirmed. In addition, this newer procedure solved another problem, i.e., rather than using mouse feeder cells it employed human feeders (Hwang WS et al 2005 Science 308:1777). These developments may assure progress toward medical use of embryonic stem cells. Some of the results, unfortunately, have been questioned and there is evidence on faking and fabricating some or much of the data. Authors have withdrawn the paper after an international uproar (Kennedy D 2006 Science 311:36) and on 20 January 2006, the Editor withdrew the invalid papers of this research group (Kennedy D 2006 Science 311:335).

The production of embryonic stem cells by somatic nuclear transfer into oocytes remained unsuccessful for primates. The failure has been attributed to an effect of the nuclear spindle in the oocyte due to maturation factor deficiency that prevented proper reprogramming of the introduced nucleus. Complete removal of the meiotic spindle from the karyoplasts was a key factor for reprogramming. Then the donor fibroblast nuclei were introduced into cytoplasts by electrofusion, incubated for 2 h to allow nuclear remodeling to occur, and subsequently activated and cultured to the blastocyst stage and 16% (35 out of 213) blastocyst formation took place. This new protocol prevented premature cytoplasm activation and maturation promoting. The rate of successful development of stem cells was relatively low but their quality appeared identical to that of embryonic stem cells. Factor decline resulted in robust nuclear envelope breakdown and premature chromosome condensation and in significantly increased blastocyst development in *Macaca mulatta* monkeys.

The earlier failures were attributed to the detrimental effect of fluorochrome bisbenzimidazole (Hoechst

33342) and ultraviolet on the relatively transparent primate oocyte. The dye and the UV light were used for the removal of the spindle. These factors apparently reduced cytoplasmic mitochondrial DNA function. The rate of successful development of stem cells was relatively low, 0.2–3.4% per oocyte and 4–10% per blastocyst but their quality appeared identical to that of embryonic stem cells (Byrne JA et al 2007 *Nature [Lond]* 450:497).

In mouse pluripotent embryonic stem cells were generated from blastocysts, which were deficient in the *Cdx2* transcription factor. Such blastocysts—generated by nuclear transfer—were unable to form functional trophoblast, necessary for the development of the implanted embryo but formed normal internal cell mass, a suitable source for pluripotent embryonic stem cells. This procedure was named ANT (for altered nuclear transfer). The mouse model thus excluded the development of embryos from the blastocysts yet provided good source of pluripotent stem cells overcoming the ethical objections—in case of humans—to destroying and manipulating embryos (Meissner A, Jaenisch R 2006 *Nature [Lond]* 439:212). Withdrawing single cells from mouse blastomeres or using trophoblast cells permits the normal development of the embryo and the isolated cells form embryonic stem cell lines with pluripotent capabilities (Chung Y et al 2006 *Nature [Lond]* 439:216). Arrested human embryos can express pluripotency marker genes such *OCT4*, *NANOG* and *REX1* and others, and can differentiate under in vitro and in vivo conditions into three germ layers. All the new lines derived from late arrested embryo have normal karyotype. Such stem cells may obviate the need for using normal embryonic stem cell lines (Zhang X et al 2006 *Stem Cells* 24:2669). Undifferentiated amniotic fluid stem cells (AFS) cells expand extensively without feeders, double in 36 h and are not tumorigenic. Lines maintained for over 250 population doublings retained long telomeres and a normal karyotype. AFS cells are broadly multipotent. Clonal human lines verified by retroviral marking were induced to differentiate into cell types representing each embryonic germ layer, including cells of adipogenic, osteogenic, myogenic, endothelial, neuronal and hepatic lineages (De Coppi P et al 2007 *Nature Biotechnol* 25:100).

Cells derived from single human blastomeres display the characteristics of embryonic stem cells and the biopsies show normal differentiation (Klimanskaya I et al 2006 *Nature [Lond]* 444:481). Adult bone marrow co-purifying with mesenchymal stem cells when injected into early blastocysts can develop into most types of cells (Jiang Y et al 2002 *Nature [Lond]* 418:41). (The results of this paper by Catherine Verfaillie laboratory was difficult to replicate by

other laboratories because of the complicated technique used [*Nature* 442:344] and there are some errors in details but the main conclusions seem valid) (Check E 2007 *Nature [Lond]* 447:763). Bone-marrow-derived stem cells regenerate into liver cells primarily after fusion with hepatocytes (Vassilopoulos G et al 2003 *Nature [Lond]* 422:901). There is evidence that bone marrow-derived stem cells develop into neurons, cardiomyocytes (heart muscle cell) and liver cells by fusion rather than by a transdetermination type mechanism (Alvarez-Dolado M et al 2003 *Nature* 425:968). Recent studies could not confirm the transdifferentiation of hematopoietic stem cell into cardiac myocytes (Murry CE et al 2004 *Nature [Lond]* 428:664; Balsam L et al *ibid.* p 668). Bone marrow-derived mesenchymal stem cells—despite their allogeneic origin—successfully repaired damage inflicted by myocardial infarction when administered through a catheter intra-myocardially in pigs, closely following the time (three days after) of the infarction. The procedure provided good healing without rejection (Amado LC et al 2005 *Proc Natl Acad Sci USA* 102:11474). Steel factor positive bone marrow-derived stem cells can repair the heart muscles by neovascularization and myogenesis after myocardial infarction in mice (Ayach BB et al 2006 *Proc Natl Acad Sci USA* 103:2304). Pluripotent murine stem cells can be converted to adipocyte lineage by bone morphogenetic protein (BMP-4) if methylation is prevented (Bowers RR et al 2006 *Proc Natl Acad Sci USA* 103:13022). A complex differentiation process converts human embryonic stem cells to endocrine cells capable of synthesizing the pancreatic hormones insulin, glucagon, somatostatin, pancreatic polypeptide and ghrelin. This process mimics, in vivo, pancreatic organogenesis by directing cells through stages resembling definitive endoderm, gut-tube endoderm, pancreatic endoderm and endocrine precursors to cells that express endocrine hormones (D'Amour KA et al 2006 *Nature Biotechnol* 24:1392).

Normal embryonic stem cells, however, can rescue mouse embryos with cardiac defects because of being deficient in the *Id* proteins, which are dominant antagonists of basic helix-loop-helix transcription factors (Fraidenraich D et al 2004 *Science* 306:247). Some postnatal rodent cardioblasts can develop into fully differentiated cardiomyocyte lines (Laugwitz K-L et al 2005 *Nature [Lond]* 433:647). Cardiac stem cells ameliorated myocardial infarction when delivered by intravascular injection in rats (Dawn B et al 2005 *Proc Natl Acad Sci USA* 102:3766) and similar observations were made in dogs (Linke A et al 2005 *Proc Natl Acad Sci USA* 102:8966). Using adenoviral virus-derived vectors and homologous recombination, defects in hypoxanthine phosphoribosyl transferase mutations could

be corrected at high efficiency in mouse embryonic stem cells by random integration within and between genes (Obhayashi F et al 2005 *Proc Natl Acad Sci USA* 102:13628).

On polymer scaffolds the development of three-dimensional structures may be facilitated (Levenberg S et al 2003 *Proc Natl Acad Sci USA* 100:12741). It is conceivable that co-transplantation of hematopoietic stem cells and stem cell for other tissues using the same donor may become feasible. In order to maintain stem cells in culture in the pluripotent state, transcription factor Oct4 and the leukemia inhibitory factor (Lif), both must be expressed. When Lif is withdrawn various types of differentiation may begin. TCF and LEF may also be important. Actually this may be regarded as a teratocarcinoma type of growth. Hypoxia (ca. 5% oxygen)—rather than normal atmospheric conditions (21% O₂)—favors the maintenance of the embryonic, pluripotent stem cell state (Ezashi T et al 2005 *Proc Natl Acad Sci USA* 102:4783).

In order to force the cells into a specific type of differentiation appropriate and special culture conditions must be established. In bone marrow-derived stem cells the presence of mesenchymal stem cells, sonic hedgehog and retinoic acid signals synergistically promote the differentiation glutamatergic sensory neuron markers (Kondo T et al 2005 *Proc Natl Acad Sci USA* 102:4789). Retinoic acid, insulin (triiodothyronine) passage may lead to the differentiation of adipocytes. Employing c-Kit (a transmembrane tyrosine kinase) + Erythropoietin may lead to the development of erythrocytes. Macrophage colony stimulating factor + IL-3, IL-1 lead to the differentiation of macrophages. Fibroblast growth factor and epidermal growth factor combinations coax the ES culture to form astrocytes and oligodendrocytes. There will be a potential for genetically engineering embryonic stem cells (ES) for special medical purposes. Undifferentiated mouse ES cells may become tumorigenic, developing into teratomas or teratocarcinomas when introduced into an animal. A rich source of embryonic stem cells is the umbilical cord at birth. Epithelial cells, hair follicles, intestinal epithelium, multipotent brain cells, hematopoietic cell may be employed as potential ES. The full clinical exploitation of stem cell technology requires technical improvements (Humpherys D et al 2001 *Science* 293:95).

On 19 December 2000, the British Parliament approved greater freedom in embryonic stem-cell research (Ramsay S 2000 *Lancet* 356:2162). On 15 June 2006, the parliament of the European Union voted for lifting the ban on funding for human embryonic stem cells (Vogel G 2006 *Science* 312:1732). In the U.S., human embryonic stem cell research can be funded by government agencies only

on the existing ca. 60 cell lines (9 August 2001). Many research workers are dissatisfied with this restriction. Although embryonic stem cells are supposed to have the potential to develop into any kind of differentiated cells—in fact, there are differences among embryonic stem cells because practically no two human beings are genetically identical—therefore, there is a need for the development of additional embryonic cell lines. (Monozygotic twins may not remain entirely identical genetically because of epigenetic changes during development). Stem cell research, thus, face great promises and great challenges; some of the problems are biological, others are ethical and regulatory. It is unfortunate that ethicists and public policy makers are not fully aware of the biology and some of the research workers are inclined to take political stands. The objection against the use of human embryonic stem cells (and destroying human embryos) could be eliminated if appropriate and effective means would be available for reprogramming somatic cells to embryonic state. One recent investigation fused human fibroblasts (2n = 46) with pluripotent embryo cells (2n = 46) into 92-chromosome cells, successfully securing their proliferation as reprogrammed somatic hybrid cells. Both component cells were appropriately marked and their fusion was verified. Similarly the embryonic state of the fusion product was established. This procedure of reprogramming would be of great significance if the chromosome number could be reduced to the normal level (2n = 46). Unfortunately, this is still a formidable obstacle to overcome (Cowan CA et al 2005 *Science* 309:1369).

There are many technical problems with human embryonic stem cell cultures because they—unlike mouse embryonic stem cells—require mouse fibroblast feeder cells and a lipid-rich bovine serum (ALBUMAX) for maintenance of stem cell condition. It appears that human cells take up from the animal products *N*-glycosyl neuraminic acid, which may cause rejection in humans if transplanted. In addition, the animal medium may transmit viruses of potential health hazard.

The mouse cells also require LIF (leukemia inhibitory factor). LIF binds a LIF receptor and glycoprotein 130, which activate the Jak/Stat3 signaling pathway sustaining the cells in undifferentiated state. These factors, however, are not sufficient for human embryonic stem cells. Human stem cells need FGF2 (fibroblast growth factor) and noggin (an inhibitor of bone morphogenetic protein, BMP) in addition to serum, to keep the human stem cells in undifferentiated state. This new medium is, however, a substantial progress in developing useful human stem cell cultures (Xu R-H et al 2005 *Nature Methods* 2:185).

No human embryos are supposed to be generated for the purpose of extracting stem cells or no fertilized and unused eggs generated by the process of in vitro artificial fertilization should be used for stem cell research. The objection to stem cell research originates from the belief that life begins at fertilization and extracting embryonic stem cells from 4–5 days old blastomeres amounts to violation of the sanctity of life (►ensoulment). The ethical problems may be dispelled if somatic stem cells occurring in placental, umbilical or fat tissues are used. Another, albeit tenuous, possibility is to generate blastomeres by inserting diploid somatic nuclei into enucleated human eggs and cloning them. Transplantation of nuclei harboring human disease genes into oocytes may make it possible to generate large quantities of embryonic tissues for laboratory studies of the mechanism and potentially the treatment of the disease. Not all cells originate from stem cells as some terminally differentiated animal cells may retain significant proliferative capacity (Dor Y et al 2004 *Nature [Lond]* 429:41). Stem cell antigen (Sca-1) is expressed in a small fraction of various cells such as of hematopoietic tissue, cardiac tissue, mammary gland, skin, muscle, testis, murine prostatic duct and the anti-apoptotic protein Bcl-2 may protect them to survive. The expression of Sca-1 and Bcl-2 may help in isolation and enriching the stem cell populations for therapeutic purposes (Burger PE et al 2005 *Proc Natl Acad Sci USA* 102:7180). Post-natal muscle-derived stem cells maintained proliferating ability for 300 doublings and displayed regenerating ability after transplantation into a mouse model of Duchenne muscular dystrophy even after 200 doublings. After that lower muscle regeneration occurred and loss of CD34 expression and loss of myogenic activity were observed. Nevertheless, this appeared a remarkable long-term self-renewal for non-embryonic stem cells (Deasy BM et al 2005 *Mol Biol Cell* 16:3323).

The exact mechanisms of the differentiation from stem cells into specific somatic cells are not entirely clear, yet compelling evidence is available for some cases of effectiveness in clinical applications. Therefore, continued research is indispensable (Quesenberry PJ et al 2005 *Science* 308:1121). In 2007, three laboratories succeeded to some extent in producing pluripotent stem cells without the use of eggs or embryos by applying specific transcription factors in culture introduced into cells by viral vectors (Okita K et al 2007 *Nature [Lond]* 448:313; Wernig M et al 2007 *Nature [Lond]* 448:318; Maherali M et al 2007 *Cell Stem Cell* 1:55). Unlike interphase zygotes, mouse zygotes temporarily arrested in mitosis can support somatic cell reprogramming, the production of embryonic stem cell lines and the

full-term development of cloned animals. Thus, human zygotes and perhaps human embryonic blastomeres may become useful for stem cell research (Egli D et al 2007 *Nature [Lond]* 447:679). Earlier researchers concluded (McGrawth J, Solter D 1984 *Science* 226:1317) that nuclei transferred to enucleated zygote cannot support development in vitro.

There are various ethical and moral problems in transplantation of human neural stem cells into animals, particularly into non-human primates. These brain cells may alter the cognitive development of animals, particularly if the implantation takes place at early embryonal or post-natal periods (Greene M et al 2005 *Science* 309:385). To overcome the objections against the use of human embryonic stem cells and avoid the adverse immunological reactions to foreign cells, in 2007, pluripotent human embryonic stem cell (hESC) lines were obtained from blastocysts of parthenogenetic origin. Parthenogenesis was chemically induced. The parthenogenetic human embryonic stem cells (phESC) demonstrate typical hESC morphology, express appropriate markers, and possess high levels of alkaline phosphatase and telomerase activity. The phESC lines had a normal 46, XX karyotype and had been cultured from between 21 to 35 passages. The phESC lines form embryoid bodies in suspension culture and teratomas after injection to immunodeficient animals and give differentiated derivatives of all three embryonic germ layers (Revazova ES et al 2007 *Cloning Stem Cells* 9:432).

Stem-Loop Structure: Any DNA or RNA that may have non-paired single strand loops associated with a double-strand stem similar to a lollipop (see Fig. S118). In the stem, the Watson-Crick pairing may not be perfect along its length. ▶palindrome, ▶repeat inverted

Figure S118. Stem-loop structure

Stem Rust: Caused by infection of the basidiomycete fungus *Puccinia graminis* on cereal plants. The haploid spores produced on the wheat plant germinate on the leaves on barberry shrubs and form pycnia (pycnidium). The pycniospores of different mating types undergo plasmogamy and form dikaryotic aecia (aecidia) on the lower surface of the barberry leaves. The aeciospores infect the wheat leaves and form the

dark brown rust pustules, called uredia. The dikaryotic uredospores reproduce then asexually and spread the disease. At the end of the growing season karyogamy takes place and the diploid teliospores are formed. The teliospores overwinter and eventually undergo meiosis and liberate the haploid basidiospores that germinate on barberry and restart the cycle. Stem rust may cause very substantial crop loss in wheat and other Gramineae. The newer varieties are genetically more or less resistant to the fungus. *P. spp* have chromosome numbers 3–6. ▶host-pathogen relationship, ▶rust

Stenosis: The narrowing of a body canal or valve such as in the aorta, heart valve, pulmonary artery, vertebral canal, etc. ▶restenosis

Stenospermocarpy: Genetically determined abortion of the embryo soon after fertilization resulting in seedless normal size berries, a desirable trait of table grapes. ▶seedless fruits

Stenting: Medical use of some device that keeps a graft or a structure in place.

Step: Single-target expression profile.

Step Allelomorphism: A historically important concept that paved the way to allelic complementation and to the study of gene structure. In the late 1920s, Russian geneticists discovered that partial complementation among allelic genes may occur in a pattern and that was inconsistent with the then prevailing idea that the gene locus is the ultimate unit of function, mutation and recombination and that alleles are stereochemical modifications of an indivisible molecule. ▶allelic complementation, ▶Offermann hypothesis; Carlson EA 1966 The gene: A Critical History. W.B. Saunders, Philadelphia, Pennsylvania.

Step Gradient Centrifugation: In the centrifuge tube usually three different concentrations of CsCl or sugar are layered without allowing mixing. The highest concentration is at the bottom of the tube. The different components of the mix, layered at the top, accumulate at the boundaries, which have higher density than the separated component.

Stepwise Mutation Model (SMM): In this model, microsatellites may change by repeated gain or loss of small number of nucleotide repeats. Electrophoretic variations of enzymes may be also fitted to such a model. ▶microsatellite, ▶infinite allele mutation model, ▶trinucleotide repeats; Moran PAP 1975 Theor Popul Biol 8:318; Ohta T, Kimura M 1973 Genet Res 22:201.

Stereocilia: Protoplasmic thin filaments like the ones in the inner ear. Whirlin, a PDZ domain protein of the

stereocilia interacts with a membrane-associated protein kinase (Ca^{2+} -calmodulin serine kinase) and erythrocyte protein p55 (4.1 R) and plays similar roles (actin cytoskeletal assembly) in erythrocytes as well as in stereocilia (Mboru P et al 2006 Proc Natl Acad Sci USA 103:10973). ▶deafness, ▶PDZ domain; Frolenkov GI et al 2004 Nature Rev Genet 5:489.

Stereoisomers: Molecules of identical composition but with different spatial arrangement.

Stereomicroscopy (dissecting microscopy): Used for visual analysis under relatively low magnification of natural specimens without sectioning. It has special advantage for dissecting structural elements with binocular viewing and top or side illumination without fixation and/or staining. ▶confocal microscopy, ▶scanning electronmicroscopy, ▶microscopy

Stereotactic: An action precisely positioned in space such as irradiation of a small spot in the body, surgical introduction of cells, a genetic vector at a defined location of the brain, etc.

Steric-Exclusion Model: This model of DNA replication states that the Watson-Crick hydrogen pairing is not an absolute necessity for the faithful replication of DNA but it is essential that the building block (not necessarily a purine or pyrimidine) would fit into the frame of the DNA double helix. A pyrene nucleoside triphosphate, with the size close to a nucleotide pair, has sufficient steric complementarity to fit into an abasic site and permits DNA replication (see Fig. S119). ▶Watson and Crick model, ▶DNA replication, ▶hydrogen pairing, ▶abasic sites; Matray TJ, Kool ET 1999 Nature (Lond) 399:704.

Figure S119. Pyrene nucleoside triphosphate

Sterigma: A small stalk at the tip of a fungal basidium where spores come off. ▶basidium

Sterile Insect Technology (SIT): ▶genetic sterilization

Sterile RNA: ▶germline transcript

Sterility: Either the male, the female, or both types of gametes (haplontic), or the zygotes (diplontic) have

reduced or no viability caused by lethal or semilethal genes, chromosomal defects, differences in chromosome numbers or incompatible cytoplasmic organelles. ▶infertility, ▶semisterility, ▶somatoplastic sterility, ▶cytoplasmic male sterility, ▶incompatibility, ▶self-incompatibility, ▶hybrid sterility, ▶azoo-spermia, ▶infertility, ▶deletion, ▶inversion, ▶translocation

Sterilization: ▶autoclaving, ▶filter sterilization, ▶pasteurization, ▶aseptic, ▶axenic, ▶radiation effects, ▶ethanol, ▶hypochlorate, ▶ethylene oxide, ▶genetic sterilization, ▶*Cochliomya hominivorax*, ▶sterilization humans, ▶birth control

Sterilization, Genetic: ▶genetic sterilization

Sterilization, Humans: Practiced by various societies for different reasons. The eunuchs of the Chinese imperial courts and of the Osmanic harems served as guardians of the privileges of tyrannical social structures. The castration of male Italian opera artistes were performed for singing in female roles, in an era when women were banned from the performing arts. In the 1880s, by the publications of Sir Francis Galton sought scientific justifications for negative eugenics in order “to produce a highly gifted race of men by judicious marriages during consecutive generations.” 1890s initiated sporadic sterilization of institutionalized, mentally retarded persons. Starting in 1907, in about 14 states (USA), laws were enacted for systematic sterilization of mentally retarded, blind, deaf, crippled or afflicted by tuberculosis, leprosy, syphilis, and chronic alcoholism. This “practical, merciful and inevitable solution” eventually degenerated into legal suggestions to eliminate criminal behavior, disease, insanity, weaklings and other defectives and “ultimately to worthless race types.” By the time strong moral objections gained noticeable ground in the year 1956, nearly 60,000 human individuals were legally sterilized. Interestingly, the Oklahoma law exempted from mandatory sterilization offenses against prohibition, tax evasion, embezzlement and political crimes. Several state laws advocated mandatory sterilization also as a guard against illegitimacy, particularly by unwed recipients of the Aid to Families with Dependent Children (AFDC). Until 1965, judicial approval could be obtained for a “good cause” for forced sterilization of mentally retarded individuals whose family had hardship in supporting the offspring of promiscuous children. Although not all states rescinded yet the old laws, sterilization of humans is now practiced only voluntarily by ligation of the vas deferens (vasectomy), tubal constriction, ovariectomy or by the use of various types of mechanical and hormonal contraceptives. Mandatory sterilization was practiced

for eugenic and social reasons in several enlightened countries (e.g., Sweden) until the 1970s. Compulsory sterilization is objectionable on moral ground because reproduction is a basic human right although the society cannot support irresponsible reproductive behavior in cases of certain genetic defects. Reproductive rights must be balanced with the right of born and unborn children with potential severe genetic load (►[wrongful birth](#))

Sterilization is particularly reprehensible when advocated as a selective measure against certain human races. The Third Reich annihilated millions and sterilized thousands for eugenic and other evil reasons. From genetic perspective it is controversial since 83% of the mentally retarded children are born to non-retarded parents. In addition, selection against the majority of human defects is quite inefficient, since the vast majority of the defective genes are in heterozygotes and many of the conditions are under polygenic control or are non-hereditary. Furthermore, there are no objective scientific or practical measures for the evaluation of most of the human traits. ►[selection](#), ►[selective abortion](#), ►[eugenics](#), ►[polygenic](#), ►[salpingectomy](#), ►[vasectomy](#), ►[ovariectomy](#); Reilly P 1977 Genetics, Law, Social Policy. Harvard University Press, Cambridge, Massachusetts.

Sternites: The ventral epidermal structures of the abdomen. ►[Drosophila](#)

Steroid 5-Beta Reductase (SRD5B1, 7q32-q33): Catalyzes reduction of bile acid intermediates and steroid hormones.

Steroid Dehydrogenase-Like Protein (NSDHL, XDq28): The mutations affect cholesterol biosynthesis and may cause male lethality. Hydroxysteroid dehydrogenase (HSD3B1, 1p13.1) deficiency may involve adrenal hyperplasia, hypospadias and gynecomastia. ►[cholesterol](#), ►[hypospadias](#)

Steroid Doping: Used by athletes to boost performance. Amphetamines increase alertness and may reduce onset of fatigue. Side effects are insomnia, exhaustion, violence and potential heart disease. The health hazards are increased if anabolic steroids, insulin, insulin-like growth hormone, etc., are used simultaneously. Even non-steroid anti-inflammatory drugs

may be risky because they mask pain and may aggravate injuries. ►[anabolic steroids](#)

Steroid Hormones: Derived by the pathway shown in Figure S120. [3] is the principal hormone of the endocrine gland, corpus luteum, in the ovarian follicle after the release of the ovum.

They regulate the expression of the secondary sexual characters of females. [4] is the main male sex hormone that is produced in 6–10 mg quantities daily in men and ca. 0.4 mg in women. It is responsible for the production of facial hair and baldness and the regulation of growth [5] is formed by oxidative removal of C-129 from its precursor; primarily a female hormone occurring in the ovaries and placenta and it is responsible for regulating, among other functions, bone growth, increased fat content and smoother skin of females compared to men. This hormone is present also in the testes. In cooperation with progesterone it regulates also the menstrual cycles. [6] and [7] are synthesized in the kidney cortex and regulate, among others, mineral (Na^+Cl^- , HCO_3^-) reabsorption and are frequently called as mineralcorticoid hormones. [8] is a glucocorticoid affecting protein, carbohydrate metabolism regulates the immune system, allergic reactions, inflammations, etc. [9] is also an anti-inflammatory glucocorticoid with a role in activating the glucocorticoid receptors. The number of steroid hormones is about 50 and they are present in practically every cell of the body, besides those mentioned, and they, along with thyroid hormones, have important roles in activation of genes. Up to 1966, the general assumption was that plants do not use steroid hormones. It has been demonstrated that brassinolids (related to cholesterol, ecdysone) mediate several developmental processes in plants, such as elongation, light responses, etc. The steroid receptor superfamily includes receptors for estrogen, progesterone, glucocorticoid, mineralcorticoid, androgen, thyroid hormone, vitamin D, retinoic acid, 9-cis retinoic acid and ecdyson. The steroid hormone receptors stimulate the formation and then stabilize the pre-initiation complex of transcription. Most commonly the condition of their binding to the hormone response element is the binding to their appropriate ligands.

Some, such as the thyroid hormone receptor, can bind to DNA in the absence of a ligand. In the

Figure S120. Steroid hormone biosynthetic pathway

absence of the ligand, they function as silencers through interaction with the TFIIB transcription factor. ▶hormone-response elements, ▶silencer, ▶PIC, ▶transcription factors, ▶transcriptional activator, ▶coactivator, ▶regulation of gene activity, ▶animal hormones, ▶estradiol, ▶aromatase, ▶plant hormones, ▶brassinosteroids, ▶anabolic steroids, ▶prenylation, ▶steroids, ▶SRC-1; Lösel R, Wehling M 2003 Nature Rev Mol Cell Biol 4:46.

Steroid Receptor: ▶hormone receptors

Steroid Sulfatase Deficiency: ▶ichthyosis

Steroidogenic Factor-1: ▶SF-1

Steroids: Contain a four-ring nucleus consisting of three six-membered rings and one five-membered ring. (See structural formula in Figure S121, ▶steroid hormones, ▶brassinosteroids).

Figure S121. General structural formula of steroids

Sterols: Lipids with a steroid nucleus. The concentration of free sterols determines the fluidity of the eukaryotic cell membranes. Esterification of sterols prevents their participation in membrane assembly. The process is mediated the ACAT complex (acyl-CoA:cholesterol acyltransferase). Increase of ACAT activity may lead to hyperlipidemia and atherosclerosis. Sterol esterification may modify the LDL receptors and potentiates atherogenic processes. The ACAT inhibitor, CP-113-818 reduces amyloid plaques in mice (Hutter-Paier B et al 2004 Neuron 44:227). It may limit intestinal sterol absorption. ▶hyperlipidemia, ▶amyloids, ▶atherosclerosis, ▶LDL, ▶membranes, ▶cholesterol, ▶SREBP, ▶phytoestrogen, ▶oxysterol; Kelley RI, Herman GE 2001 Annu Rev Genomics Hum Genet 2:299; Xu F et al 2005 Proc Natl Acad Sci USA 102:14551.

Stevens-Johnson Syndrome (toxic epidermal necrolysis susceptibility, 6p21.3): The drugs carbamazepine, phenobarbital and allopurinol may evoke cutaneous blistering, epidermal detachment, fever and potentially death. Han Chinese people are more likely to show this reaction than Caucasians. The major histocompatibility complex Class I B5801 allele may be responsible for it. ▶allopurinol, ▶gout, ▶HLA; Hung S-I et al 2005 Proc Natl Acad Sci USA 102:4134.

stg (string, map position 3-99): *Drosophila* gene locus controlling the first ten embryonic divisions (similarly to gene *Cdc28* in *Schizosaccharomyces pombe*); it is a cyclin gene. ▶cell cycle

Stick-and-Ball Model: A representation of chemical structure (see Fig. S122).

Figure S122. Stick- and ball model

Stickiness of Chromosomes: Observed as some sort of adhesion between any chromosomes within a cell. ▶side-arm bridge

Stickleback (*Gasterosteus aculeatus*, $2n = 42$ visible chromosomes, XXIII linkage groups): Small, common fresh and seawater fish (see Fig. S123). (See <http://cegs.stanford.edu/index.jsp>).

Figure S123. Stickleback

Stickler Syndrome (arthroophthalmopathy, AOM): An early and strong progressive myopia (nearsightedness) and hearing deficit. Retinal detachment may result in blindness, caused probably by a dominant mutation in the collagen (COL11A1) gene (human chromosome 1p21). Overlapping mutations are responsible for the Marshall syndrome at 1p21. Stickler syndrome 3 is located at 6p21.3. The collagen type II (COL2A1, 12q13.11-q13.2) defects of the Stickler syndrome involve achondroplasia, skeletal dysplasia, eye and hearing defects. ▶collagen, ▶eye disease, ▶connective tissue disorders, ▶skin diseases; Annunen S et al 1999 Am J Hum Genet 65:974; Richards AJ et al 2000 Am J Hum Genet 67:1083.

Sticky Ends: Double-stranded DNA with a single-stranded overhang to what complementary sequences

are available and so they can stick by base pairing (see Fig. S124).

Figure S124. Sticky ends

Stigma: The tip of the style that is normally receptive to the pollen of plants. In zoology, it means spot, such as a hemorrhagic small area on the body. ▶gametophyte female, ▶gametophyte male, ▶protogyny, ▶protandry

Stigmasterol: A plant lipid derivative formed by methylation of ergosterol. For guinea pigs, it is a vitamin necessary to avoid stiffness of the joints. ▶ergosterol, ▶cholesterol

Stilbene: ▶resveratrol

Still-Birth: The birth of a dead offspring. It is caused by chromosomal defects in ca. 7% of the stillborn or by other pathological conditions. ▶chromosomal breakage

Stipule: A leaf like bract at the base of a leaf (see Fig. S125).

Figure S125. Stipules

Stk: A macrophage-stimulating factor receptor. ▶macrophage

STM: ▶scanning tunneling microscope

Stn1: A telomere length determining protein factor of yeast working in concert with Cdc13. ▶Cdc13; Grandin N et al 1997 Genes Dev 11:512.

Stochastic: Corresponds to a random process; a process of joint distribution of random variables. In a population—in contrast to a deterministic model—random

drift and other chance events may determine the gene frequencies. Mutations are assumed to occur at random, and selective forces acting upon these random alterations shape evolution. Generally, deterministic and stochastic processes run parallel and simultaneously. ▶deterministic model

Stochastic Detriment of Radiation: The combined risk of cancer, genetic damage and life shortening due to radiation exposure. The figures may vary according to tissues: for gonads it may be 1.33, for bone marrow 1.04, for breast 0.24, for liver 0.16 (in 10^{-2} Sv^{-1}), etc. ▶radiation hazards

Stock: A genetically defined strain of organisms; also a root stock on what a scion is grafted.

Stock, Garden (*Matthiola incana*): ▶*Matthiola*

Stoke: A unit of kinematic viscosity (the ratio of viscosity to density). ▶viscosity

Stolon: A horizontal underground stem such as the tuber-bearing structures of potatoes.

Stoma (plural stomata): A small pore on the leaf surface surrounded by two guard cells, which control opening and closing. Basic helix-loop-helix proteins under the control of three genes (Plitteri LJ et al 2007 Nature [Lond] 445:501) control stoma differentiation, although several other factors also have regulatory role. The stoma permits gas exchange (CO_2 uptake), and release of water vapors (transpiration). The opening of the stomata requires an increase in the turgor of the guard cells (see Fig. S126). It had been suggested that the process could be promoted by opening of K^+ and Cl^- channels and the subsequent influx of K^+ and Cl^- . A light controlled proton pump activates the opening of the K^+ channel. The closure of the stomata is controlled by the hormone ABA and the influx of Ca^{2+} and the efflux of K^+ and Cl^- .

Figure S126. Open stoma

The calcium level is sensed by a cyclin-dependent protein kinase (CDPK). Blue light photoreceptors *CRY1* and *CRY2* and phototropin genes *PHOT1* and *PHOT2* receptors regulate blue light response but the quadruple mutants *cry1*, *cry2*, *phot1*, *phot2* mutants barely responded. Mutation in COP1 (constitutive photomorphogenesis) permitted opening of the stomata in darkness and in blue light the triple

recessive mutants displayed open stomata (Mao J et al 2005 Proc Natl Acad Sci USA 102:12270). Pattern of stoma development is controlled by a MAPKK kinase (Bergmann D et al 2004 Science 304:1494).

Erecta mutants (*er*, *erl1*, *erl2*) defective in the regulation in leucine-rich repeat receptor kinases cause clustering of the guard cells of the leaves (see Fig. S127) (Shpak ED et al 2005 Science 309:290). Besides stoma density in the *erecta* mutants, epidermal cell expansion, mesophyll cell proliferation and cell-cell contacts regulate transpiration and photosynthesis in plants and determine the efficiency of carbon fixation (Masle J et al 2005 Nature [Lond] 436:866). (For the phenotype of *er/er* see ▶*Arabidopsis thaliana* entry.)

In the regulation of stomata, Ca^{2+} -dependent ATPases and GTPases have major role. The processes involve changes in the electric potentials (depolarization). In the control of the ABA response, syntaxin-like proteins play a role. Sphingosine-1-phosphate level signals to calcium mobilization. Phospholipase D α 1-produced phosphatidic acid signals to abscisic acid-promoted stomatal closure. Phospholipase D α 1 and phosphatidic acid interact with the G α subunit of the heterotrimeric G protein to mediate abscisic acid inhibition of stoma opening (Mishra G et al 2006 Science 312:264). Open stomata provide passive entry for bacterial infection of plants. Stomatal guard cells—as an innate immune reaction—perceive bacterial surface molecules by the FLS2 receptor, production of nitric oxide and guard cell-specific OST1 kinase and respond with stomatal closure. Some plant pathogenic bacteria have developed, however, a virulence mechanism for reopening the entry port (Melotto M et al 2006 Cell 126:969). ▶ion channels, ▶cell cycle, ▶aequorin, ▶calmodulin, ▶cyclin, ▶ATPase, ▶MAP kinase, ▶GTPase, ▶proton pump, ▶ABA, ▶abscisic acid, ▶phospholipase,

▶syntaxin, ▶sphingolipids, ▶G protein, ▶abscisic acid, ▶phosphatidate, ▶host-pathogen relation; Blatt MR 2000 Annu Rev Cell Dev Biol 16:221; Schroeder JI et al 2001 Nature [Lond] 410:327; Wang X-Q et al 2001 Science 292:2070; Schroeder JI et al 2001 Annu Rev Plant Physiol Plant Mol Biol 52:627; Hetherington AM 2001 Cell 107:711; Nadeau JA, Sack FD 2002 Science 296:1697; Hosy E et al 2003 Proc Natl Acad Sci USA 100:5549; Hetherington AM, Woodward FJ 2003 Nature [Lond] 424:901.

Stomatin: A cation conductance protein in the cell membrane. ▶anesthetics

Stone: ▶scaffolds in genome sequencing

Stop Codon: ▶nonsense codon, ▶genetic code

Stop Signal: ▶transcription termination in eukaryotes, ▶transcription termination in prokaryotes, ▶stop codon, ▶release factor [RF]

Stoppers: Mitochondrial mutations in *Neurospora* displaying stop-start growth. ▶poky

STP: ▶signal transfer particle

STP β (second strand transfer protein): ▶recombination mechanisms eukaryotes, ▶Sep 1

STR: Short/single tandem repeats, such as found in micro- and minisatellites. Using the profiles of only 13 STRs it is possible to provide a rapid test for crime scenes; STR are used for forensic analysis and for population studies. ▶microsatellite, ▶minisatellite, ▶forensic genetics, ▶DNA fingerprinting

Strabismus: An anomaly of the eyes; they may be either divergent or convergent or one directed up, the other down because of the lack of coordination of the muscles concerned. Some persons display this anomaly only periodically. The pattern of inheritance is not entirely clear; most likely dominant factor(s) are involved. The recurrence among the offspring of convergent probands is higher than that among children of the divergent type. Its incidence in the general population is ~ 0.002 . ▶eye diseases, ▶Duane retraction syndrome, see Fig. S128.

Figure S128. Strabismus

Figure S127. Rosette leaf epidermis wild type (left) and *erecta* triple mutant (right). Stomata express GUS activity. (Courtesy of Drs. Jessica McAbee and Keiko Tori)

Strain: An isolate of an organism with some identifiable difference from other similar groups. This term does not imply any stringent other criteria.

Strain Distribution Pattern (SDR): The distribution of two alleles of a diploid among the progeny where linkage is studied either by a backcross or by recombinant inbred procedure. ▶backcross, ▶linkage, ▶recombinant inbred

Strand Assimilation: The *exo* gene of lambda phage codes for a 5'-exonuclease (M_r 24,000) that can convert a branched DNA structure to an unbranched nicked duplex by the process called strand assimilation during recombination. A progressive incorporation of one DNA strand into another during recombination (•••••) (see Fig. S129). ▶recombination, ▶lambda phage

Strand Bias: ▶gene distribution

Strand Displacement: A type of viral replication involving the removal of the old strand before the new strand is completed. Similar mechanism is used by mtDNA, ▶D loop

Stratification: Layering; in statistical analysis studying the population by, for e.g., age groups, ethnicity or other suitable attributes besides some other criteria of comparison, such as onset of a disease. Stratification may lead to false positive association; comparison of gene frequencies among population mandates appropriate case controls. Principal component analysis and stratification is used by the method of Eigenstrat for minimizing spurious associations in disease studies (Price AL et al 2006 Nature Genet 38:904). Lactase persistence and tall stature was strongly associated in Americans of European descent (Campbell CD et al 2005 Nature Genet 37:868). ▶lactose intolerance, ▶case control, ▶descent; Hoggart CJ et al 2003 Am J Hum Genet 72:1492; Reich DE, Goldstein DB 2001 Genet Epidemiol 20:4.

Stratification Artefact: The disease and control alleles dealt with are from different (ethnic) populations in case-control studies. Sib, parent or other family comparisons may correct the problems. Lower gene frequencies favor reliable result. ▶case—control method

Stratified Random Sample: Represents the entire population (including subpopulations) in a reliable manner.

Stratocladistics: The study of evolution on the basis of fossil records. It minimizes the significance of homoplasy and lack of preservation of lineages that would preserve other lineages under examination. ▶cladistic

Strauss Family: Viennese composers and conductors of three generations. Johann Strauss the Elder (1804–1849) became celebrated for his light waltzes and other dance music. His son Johann Strauss the Younger (1825–1899) is the author of the Blue Danube and many other waltzes was the most celebrated composer (see Fig. S130). His brothers Josef Strauss (1827–1870) and Eduard Strauss (1835–1916) were also famous conductors and composers. Son of Eduard, Johann (1866–1939) was also a renowned conductor. ▶musical talent

Figure S130. Johann Strauss Jr.

Strawberry (*Fragaria ananassa*): About 46 *Fragaria* species with $x = 7$; the wild European *F. vesca* is diploid ($2n = 14$), *F. moschata* ($2n = 42$), some east Asian species are tetraploid, the American strawberries as well as the garden strawberries are $2n = 56$. (See <http://bioinformatics.pcbasc.latrobe.edu.au/index.htm>).

Streak (primitive streak): A sign on the early embryonal disc indicating the movement of cells and the beginning of the formation of the mesoderm and an embryonal axis. ▶organizer

Streking: Spreading microbial cells on the surface on a nutrient agar medium to observe growth or lack of it. (See Fig. S131).

Figure S129. DNA strand assimilation

Figure S131. Streaking of wild type (left top) and mutant strains of yeast

Streptavidin: Conjugated with rhodamine, it specifically binds to biotin (biotinylated nucleic acids, immunoglobulins) and permits their detection by fluorescence. The binding constant for biotin is $k_a = 10^{15} \text{ M}^{-1}$.
 ►avidin

Streptavidin-Peroxidase: Identifies biotinylated antibodies in ELISA, in immunochemistry in general and in protein blots. ►genomic subtraction, ►ELISA, ►biotinylation

***Streptococcus pneumoniae* A (*Diplococcus pneumoniae*):** The common pathogenic bacterium causing pharyngitis (sore throat) (see Fig. S132). About 5–10% of the infections may involve necrotic lesion of various severities. In rare extreme cases, it may cause death. Some strains secrete substantial amount of a pyrogenic (fever-producing) exotoxin A, which stimulates the immune system as a superantigen. The excessive stimulation results in the overproduction of cytokines that may damage the lining of the blood vessels and thus cause fluid leakage, reduced blood flow and necrosis of the tissues because of the lack of oxygen. As a further consequence, fasciitis (inflammation of the fibrous tissues) and myositis

(inflammation of the voluntary muscles) may follow. Immunity to *S. pneumoniae* may be independent of the capsular antigens and protection requires the presence of CD4^+ T cells at the time of infection (Malley R et al 2005 Proc Natl Acad Sci USA 102:4848).

The destruction of the tissues may result in death within a very short period after infection by the extremely virulent strain of “flesh-eating bacteria.” *Streptococcus* (B) *agalactiae* is a serious threat to diabetic, cancerous or elderly people; it may be responsible for neonatal sepsis occurring during vaginal delivery. *Streptococcus pneumoniae* (*Pneumococcus*) provided the first information on genetic transformation in 1928. Its sequenced genome (in 2001) of 2,160,837 bp contains 2236 ORFs (see Fig. S133). Approximately 5% of its genome is insertion sequences. The completely sequenced genome of *S. pyogenes* M1 has 1,852,442 bp and encodes ~1752 proteins. *Streptococcus mutans* UA159, the major cause of tooth decay contains 2,030,936 bp and 1963 ORF; its genome has several insertion elements and transposons. Group B *Streptococcus* pathogens display multiple serotypes and they are life threatening to newborns in the first week after birth. The infection comes generally from the healthy mothers who (in 25–40%) harbor the bacteria in anogenital area. This bacterium as many other pathogens are resistant to several antibiotics. Vaccine production has problems because of the serotype variation. However, four proteins provide rather general type of protective antibodies against the various types of *Streptococcus* B bacteria. The protective antibody (immunoglobulin G, IgG) is transmitted to the baby through the placenta (Maione D et al 2005 Science 309:148). ►transformation genetic, ►necrosis, ►superantigen, ►toxic shock syndrome, ►streptolysin, ►fratricide, ►host-resistance genes; Tettelin H et al 2001 Science 293:498; Ferretti JJ et al 2001 Proc Natl Acad Sci USA 98:4658; Hoskins J et al 2001 J Bacteriol 183:5709; Tettelin H et al 2002 Proc Natl Acad Sci USA 99:12391; Ajdic D et al 2002 Proc Natl Acad Sci USA 99:14434.

Figure S132. *Streptococcus* exudates on tonsils appear as white spots in severe sore throat. (Modified after Nimishikavi S & Stead L 2005 New England J. Med. 352: p e10)

Figure S133. *Streptococcus* colonies; Single cell at high magnification

Streptokinase: An activator of plasminogen. ►[plasminogen activator](#), ►[plasmin](#)

Streptolygidin: An antibiotic that blocks the action of prokaryotic RNA polymerase.

Streptolysin: A cholesterol-binding bacterial exotoxin, which forms large holes through the mammalian plasma membrane. At low concentration, it is suitable for introducing proteins through living cell membranes without irreversible damage to the cell. Streptolysin O prevented *Streptococcus* internalization into lysosomes, killing the extracellular pathogen (Håkansson A et al 2005 Proc Natl Acad Sci USA 102:5192). ►[cytolysin](#); Walev I et al 2001 Proc Natl Acad Sci USA 98:3185.

Streptomyces: A group of Gram-negative bacteria of the actinomycete group, characterized by mycelia-like septate colonies. On these mycelial colonies spore-bearing organs develop. These bacteria somewhat simulate a multicellular type of development. Their genetic material, unlike the majority of prokaryotes, is a linear DNA. The sequenced genome of *S. coelicolor* A3(2) is 8,667,507 bp, containing an estimated 7825 genes (Bentley SD et al 2002 Nature [Lond] 417:141). *S. avermitilis* has linear chromosome built of 9,025,608 bp encoding at least 7574 open reading frames (Ikeda H et al 2003 Nature Biotechnol 21:526; chromosome: Hopwood D 2006 Annu Rev Genet 40:1).

Streptomycin: An antibiotic compound, precipitates nucleic acids, inhibits protein synthesis and interferes with proofreading, and thus causes translational errors (see Fig. S134). Mutation in its S12 ribosomal protein binding sites leads improved translational precision. Some mutations may lead to streptomycin-dependence. Streptomycin resistant mutations in the

ctDNA are maternally inherited; such mitochondrial DNA mutations may lead to hearing loss in humans. ►[antibiotics](#), ►[mitochondrial diseases in humans](#), ►[mtDNA](#)

Streptozotocin (a nitrosamide, 2-deoxy-2-[3-methyl-3-nitrosoureide]-D-glucopyranose): A methylating, carcinogenic, antibiotic agent (effective even against fungi). Induces diabetes and poisons B lymphocytes.

Stress: A condition when living beings must cope with difficult mental or physiological conditions. A major gene duplication for panic and phobic disorders appeared to be at human chromosome 15q24-q26 but another study failed to confirm this finding (Taberner M et al 2003 Am J Hum Genet 72:535). Stress or anxiety activates the corticotropin releasing factor (CRF/CRH) synthesis in the hypothalamus. CRF then stimulates the CRF receptors (CRHR) in the pituitary and this turns on the adrenocorticotropin hormone (ACTH) in the kidneys leading to the production of glucocorticoids, which hinder by feedback to the brain the stress reaction. In case of a failure to respond successfully with some type of a homeostatic mechanism, death or substantial harm may result. Phosphoinositide 3-kinase (PIK) related kinases mediate a variety of cellular stress responses (Bakkenist CJ, Kastan MB 2004 Cell 118:9). Stress activates sphingomyelinase to generate ceramide and the latter initiates apoptosis. Disruption of the glucocorticoid receptor gene may lead to reduced anxiety. Stress also activates heatshock proteins and glucose-regulated proteins (GRP). The GRP proteins are highly active during tumor progression. Their suppression may lead to apoptosis and rejection of the tumor cells. The stress signals may mediate the activation of genetic repair systems or, in animals, may proceed through three main pathways, the c-Abl or the JNK or the p53 routes. The first two are specific to different types of genotoxic agents, the p53 protein responds rather generally to various chemical stresses. The signal transducers eventually reach the DNA by the activation of transcription factors. Ionizing or excitatory (UV) radiations may directly cause chromosome breakage resulting in either repair or apoptosis. In plants, stress stimulates the formation of elicitors and pathogenesis-related proteins. *Arabidopsis* plants exposed to ultraviolet radiation (UV-C), to stress caused by infection by pathogens, or to flagellin, displayed increased level of homologous somatic recombination; the genomic instability persisted in following generations and the condition was transmitted as a dominant trait by both female and male gametes to progeny (Molinier J et al 2006 Nature [Lond] 442:1046). ►[homeostasis](#), ►[p38](#), ►[GADD153](#), ►[CAP](#), ►[ceramides](#), ►[sphingolipids](#), ►[sphingolipidoses](#), ►[SAP](#), ►[SAPK](#), ►[apoptosis](#),

Figure S134. Streptomycin

►JNK, ►cAbl, ►p53, ►pathogenesis-related proteins, ►heat-shock proteins, ►adrenocorticotrophic hormone, ►human brain, ►glucocorticoid, ►drought resistance, ►salt tolerance, ►host-pathogen relations, ►flagellin, ►ultraviolet light, ►instability genetic, ►Pik; Smith MA et al 1995 Proc Natl Acad Sci USA 92:8788; Gratacòs M et al 2001 Cell 106:L367; Dolan RJ 2002 Science 298:1191.

Stress Granules: May accumulate in mammalian and other cells under physical or chemical stress and regulate metabolism (Andreson P, Kedersha N 2006 J Cell Biol 172:803).

Stress Proteins: Most commonly mean heat shock proteins. ►heat-shock protein

Stretching Chromosomes: For more precise localization of FISH labels the chromosome can be extended 5–20 times their highly coiled length using hypotonically treated, unfixed metaphase chromosomes and centrifugation. ►FISH; Bennink ML et al 2001 Nature Struct Biol 8:606.

Striated Muscles: The heart and skeletal muscles are made of sarcomeres and thus striated transversely. ►smooth muscles

Striatum: A layered tissue region, e.g., in the subcortical area of the brain where cognitive and movement regulation functions are mediated. ►brain human

STRING (search tool for the retrieval of interacting genes/proteins): ►genetic network; <http://string.embl.de/>.

String Edit Distance: Determined upon addition, deletion or replacement one base symbol in order to transform a DNA sequence (a string) into another. ►tree edit distance

Stringent: Rigidly controlled.

S

Stringent Control: In amino-acid-starved bacteria (auxotrophs), the product of the *relA*⁺ gene shuts off ribosomal RNA synthesis as an economical device. In the presence of *relA* amino acid synthesis is promoted (relaxed control) because ppGpp regulates the discriminator regions of the promoters. ►fusidic acid, ►relaxed control, ►discriminator region, ►ribosomes; Chatterji D et al 1998 Genes Cells 3:279; Chatterji D, Ojha AK 2001 Curr Opin Microbiol 4:160; Barker MM et al 2001 J Mol Biol 305:673.

Stringent Genomes: These are the nuclear ones because each chromosome is normally replicated once during the cell cycle and normally during mitosis, each member of a diploid (or other euploid) chromosome set is partitioned equally between the daughter cells. ►relaxed genomes

Stringent Plasmid: The low copy number of it is genetically controlled.

Stringent Replication: Limited replication of the low copy number plasmid DNA.

Stringent Response: Under poor growth condition prokaryotic cells may shut down protein synthesis by limiting tRNA and ribosome formation. The synthesis of the *rrn* genes is mediated by binding ppGpp or pppGpp sequences to the *rrn* promoters. Proteins DksA or GreA and Mdf are also regulators (Trautinger BW et al 2005 Mol Cell 19:247). ►stringent control, ►magic spot, ►rrn, ►ribosomes, ►transfer RNA, ►guanosine tetraphosphate, ►Rel oncogene; Chatterji D Ojha AK 2001 Curr Opin Microbiol 4(2):160; van Delden C et al 2001 J Bacteriol 183:5376.

STRL: Co-receptor of HIV and SIV. ►acquired immunodeficiency syndrome

stRNA: ►RNAi, ►microRNA

Stroke: see <http://www.stroke-statement.org/>; ►HuGENet, ►risk

Stroke: Causes 150,000 death/year and afflicts three times as many in the USA. Stroke results from occlusion of a cerebral artery. A mouse model indicates that newborn neurons can migrate to the ischemic regions and may affect recovery in some cases (Jin K et al 2006 Proc Natl Acad Sci USA 103:13198). The major genetic factors involved are telangiectasia, the Osler-Weber-Rendu syndrome, CADASIL, Ehlers-Danlos syndrome, polycystic kidney disease, Marfan syndrome, cardiovascular diseases, hypertension, MELAS syndrome. Gretarsdottir, S. et al (2002 Am J Hum Genet 70:593) reported a susceptibility locus at 5q12 encoding phosphodiesterase 4D acting probably through atherosclerosis in ischemic stroke (Gretarsdottir S et al 2003 Nature Genet 35:135). The genetic association of stroke with the *PDE4* marker or SNP45 could not be generally replicated not due to entirely clear bases, but because of the complexity of the major types of stroke (ischemic [blockage of vessels by blood clots], hemorrhagic [rupture of blood vessels] or other subtypes [cardiogenic or large vessels]) may account for the discrepancies (Rosand J et al 2006 Nature Genet 38:1091; Gulcher JR et al 2006 Nature Genet 38:1092). Protein kinase PRKCH appears to be liable for the pathogenesis of cerebral infarction in Japanese populations (Kubo M et al 2007 Nature Genet 39:212). (See terms mentioned under separate entries).

Stroma: The aqueous solutes within an organelle. A pseudoparenchymatous association of fungal mycelia is also so named. The supportive tissue of an organ;

stroma cells in the bone marrow may produce collagen and extracellular matrix. ► **parenchyma**

Stroma Cell-Derived Factor-1 α : A chemoattractant for hematopoietic stem cells and has role in cell migration within or to the bone marrow. It may affect cell proliferation and cell migration in cancer metastasis.

Stromelysin: ► **metalloproteinases**, ► **transin**

Strong-Stop DNA: When reverse transcriptase initiates transcription of the first strand DNA—from the RNA—then a second strand is made on the first strand DNA template. The transcriptase pauses after the transcription of the R U5 segments (first strand). The U5 R, U3 (second strand) “strong stop” DNA species accumulate (in the latter case including small portions of the RNA primer) before transcription continues to completion of the first, and then of the second strand, respectively. ► **retroviruses**, ► **reverse transcriptase**; Driscoll MD et al 2001 J Virol 75:672.

Strontium: An earth metal with several isotopic forms, the ^{90}Sr , a β -emitter radioactive component of nuclear fallout is readily substituted for calcium and, thus, may be concentrated in the milk if the cows grazed on contaminated pastures. Its half-life is 28 years. After the bomb testings in the 1950s, it became especially threatening to children whose bones accumulated 2.6 μCi in contrast to adults (0.4 μCi). ► **radiation hazards**, ► **Ci**, ► **isotopes**

STRP: Short tandem repeat polymorphism. ► **microsatellite**

Structural Classification of Proteins: ► **SCOP**, ► **ASTRAL**

Structural Gene: A primarily non-regulatory DNA sequence that codes for the amino acid sequence in a protein or for rRNA and tRNA.

Structural Genomics: Develops high-resolution models of protein structure in order to understand catalytic and other functional mechanisms, ligands, domains, reveal critical targets for site-directed mutagenesis, and develop means for therapeutic interventions. The main tools are x-ray crystallography and nuclear magnetic resonance analysis. (See Baker D, Sali A 2001 Science 294:93; <http://www.nysgrc.org/>).

Structural Heterozygosity: Involves normal and rearranged homologous chromosomes within cells. ► **inversion**, ► **translocation**, ► **aberration chromosomal**

Structural Variants of Chromosomes: involve deletions, duplications, inversions, transpositions, translocation, complex rearrangements and copy number variations. The Database of Structural Variants of the human genome in 2007 includes a total of 29,289

entries. Among those 11,784 were copy number variants of 4357 loci, 182 inversions, and 17,323 indels (<http://projects.tcag.ca/variation/>). These variants are more numerous than initially expected and seriously affect the function of many loci. Paired-end mapping (PEM) is an effective means for their identification. PEM involves the preparation and isolation of paired ends of 3 kb fragments and their massive sequencing with 454 technologies and computationally. In two individuals 1300 structural variants (SVs) were identified suggesting that humans may differ to a greater extent in SVs than in single nucleotide polymorphism (Korbel JO et al 2007 Science 318:420). ► **paired-end sequence method**; 454 sequencing: <http://www.454.com/products-and-reagents/genome-sequencer.asp>.

Structure-Directed Combinatorial Mutagenesis: PCR-based mutagenesis.

Strumpell Disease: ► **spastic paraplegia**

STS: ► **sequenced tagged sites**

STS-Content Mapping: In physical mapping, the large sequences used (YAC clones) contain STS tracts and thus their position can be mapped. ► **sequenced tagged sites**, ► **YAC**; Chen YZ et al 2001 Genomics 74:55.

Stuart Factor Deficiency: ► **prothrombin deficiency**, ► **antihemophilic factors**

Student's *t* Distribution: A statistical test for assessing a hypothesis about the means of two populations. This distribution enables the statisticians to compute confidence limits for μ (the true mean of a population) when σ (the standard deviation of the true mean) is not known, and only the standard deviation of the sample s is available.

The quantity of t is determined by the equation:

$$t = \frac{\bar{X} - \mu}{s/\sqrt{n}}$$

where \bar{X} is the experimental mean and n is the population size. The critical t values are generally read from statistical tables after it had been quantified by the calculated t value,

$$t = \frac{d}{\sqrt{V}}$$

where d is the difference between means and V is variance. Under practical conditions the significance of the difference between two means is calculated by

the formula $t = (\bar{x}_1 - \bar{x}_2) / \sqrt{[s_1]^2 + [s_2]^2}$ where the x values stand for the two means and s^2 values are the variances of the two populations. ► **arithmetic mean**, ► **standard deviation**, ► **variance**, ► **paired *t* test**, see Table S5.

Table S5. The calculated value at the determined degrees of freedom (*df*) must be identical or greater than the closest value found on the pertinent *df* line in order to qualify for the probability shown at the top of the columns. E.g., for *df* = 10, and *t* = 3.169 *P* = 0.01 but if the *t* would be only 3.168 *P* would be only 0.05 according to table and statistical conventions. The use of *t* charts or linear interpolation using the logarithms of the two-tailed probability values (Simaika 1942 Biometrika 32:263) can obtain more precise *P* values. Remember that the *t* test indicates the probability of the null hypothesis that the two means would be identical

| <i>df</i> | <i>P</i> → 0.900 | 0.500 | 0.400 | 0.300 | 0.200 | 0.100 | 0.050 | 0.010 | 0.001 |

Study Bias: A difference in being studied because of a certain property of the entity attracted more interest for research workers.

Stuffer DNA: Part of the phage λ genome is not entirely essential for normal functions of the phage. Sequences between gene *J* and *att* representing about one-fourth of the genome can be removed and replaced (stuffed in) by genetic engineering without destroying viability of the phage. ► [lambda phage](#), ► [vectors](#); Parks RJ et al 2001 J Virol 73:8027.

Sturge-Weber Syndrome (phakomas): Ektodermal hamartomas, angiomas of the meninges. ► [hamartoma](#), ► [angioma](#), ► [meninges](#), ► [von Hippel-Lindau disease](#), ► [tuberous sclerosis](#)

sturt: The unit of fate mapping; named after Alfred Sturtevant who first used fate mapping. ► [fate maps](#)

Stutter Bands: DNA slippage may occur during PCR replication, (especially of long dinucleotide repeats) and may create shorter sequences than expected, making the identification of the heterozygotes for microsatellite sequences difficult. ► [microsatellite](#), ► [PCR](#); Miller MJ, Yuan BZ 1997 Anal Biochem 251:50; Walsh PS et al 1996 Nucleic Acids Res 24:2807.

Stuttering: A transcription termination phenomenon; poly U may easily break U-A associations. ► [stammering](#)

Stylopodium: The bones of the humerus and femur.

Stylus (style): The slender structure leading from the stigma to the ovary of plants through which the pollen tube grows to the embryosac. ► [gametophyte female](#), ► [gametophyte male](#)

su1 = supD, su2 = supE, su3 = supF, su4 = supC, su5 = supG and su7 = supU: ► [su⁻](#)

su⁻: The wild type allele of a suppressor mutation; the suppressor allele is *su⁺*.

su⁺: The suppressor allele at a locus in contrast to the wild type that is designated *su⁻*.

Su Blood Type: Occurs in pigs and resembles the Rh blood type in humans. ► [Rh blood type](#), ► [erythroblastosis fetalis](#)

Subcellular: An organelle or other structure or site within a cell. (See subcellular localization of mouse proteins: <http://locate.imb.uq.edu.au/>; proteins of several organisms: <http://bioinformatics.albany.edu/~ptarget>; <http://gpcr.biocomp.unibo.it/esldb/>; Arabidopsis subcellular proteins: <http://www.suba.bcs.uwa.edu.au>).

Subcellular Localization: The expression levels of many genes are correlated with their subcellular site(s). Gene expression level is generally high in the cytoplasm, low in the nuclear membrane, and intermediate level in the secretory pathways (endoplasmic reticulum and Golgi). In each group fluctuations occur. It has been estimated that in yeast, 47% of the proteins are located in the cytoplasm, 13% in the mitochondria, 27% in the nucleus and nucleolus, and 13% in the endoplasmic reticulum and secretory vesicles (Kumar A et al 2002 Genes Dev 16:707). ► [mitochondria](#), ► [mitochondrial diseases in humans](#), ► [chloroplast genetics](#), ► [FL-REX](#), ► [gene ontology](#), ► [organelle](#), ► [tissue-specificity](#); Drawid A et al 2000 Trends Genet 16:426; Feng Z-P, Zhang C-T 2002 Int J Biochem Cell Biol 34:298; protein targeting signals: Schneider G, Fechner U 2004 Proteomics 4:1571; Gene Ontology Molecular Function and Subcellular Localization: <http://www.cs.ualberta.ca/~bioinfo/PA/GOSUB/>; subcellular localization of mammalian proteins: <http://locate.imb.uq.edu.au/>.

Subcloning: Recloning a piece of DNA. ► [cloning molecular](#), ► [cloning vectors](#)

Subculturing: Transferring of a culture into a fresh medium.

Subcutaneous: Beneath/under the skin.

Suberin: A corky, complex polymeric material (of fatty acids but no glycerol associated with it) on the surface and within plant cells. In many plants, there is a subepidermal layer of suberin in air-filled cells and in various scar tissues. Suberin is frequently associated with cellulose, tannic acid, dark pigments (phlobaphenes) and inorganics. The commercial cork produced by the oak, *Quercus suber*, is suberin. ► [host-pathogen relation](#)

Subfunctionalization: Gene duplication involving somewhat different function of the duplicated copy, e.g., expression at a different location of the body. In *Arabidopsis* and *Antirrhinum*, the *AGAMOUS* and the *PLENA* genes, respectively, descended in a non-orthologous manner from the *SHATTERPROOF* and *FARINELLI* genes, respectively (Causier B et al 2005 Curr Biol 15:1508). Subfunctionalization model assumes that the paralogous genes are selectively neutral and thus permitted to mutate and explore new adaptive functionalities without extinction. Eventually, one of the copies may be converted to the status of pseudogenes or is entirely lost. The duplicated genes may have lost one of the function, therefore, both copies became necessary and favored by evolution or they might be preserved by drift.

►duplication, ►paralogous, ►pseudogene, ►neofunctionalization; Force A et al 1999 *Genetics* 151:1531; Tochini-Valentini GD et al 2005 *Proc Natl Acad Sci USA* 102:8933.

Sublethal: Only about 50% of the affected my live until sexual maturity.

Sublimon: Sub-stoichiometric molecules of mtDNA that are supposed to be the products of recombination within short repeated sequences in this organelle. ►mtDNA; Kajander OA et al 2000 *Hum Mol Genet* 9:2821.

Subline: New colony of rodents set up in a new laboratory. ►substrain, ►inbred

Submetacentric: Chromosome with two arms clearly unequal in length (see Fig. S135). ►chromosome morphology

Figure S135. Submetacentric

Submission: ►data submission standards

Submission Signal: In the majority of vertebrates, aggressive behavior generally ends when the weaker partner in the conflict displays the submission signal, e.g., dogs lie on their back. The human race does not employ such definite signals and thus, the conflicts frequently end in violence. ►aggression, ►behavior genetics, ►human behavior, ►ethology

Subspecies: A group of organisms within a species distinguishable by gene frequencies, chromosomal morphology and/or rearrangement(s), and may show some signs of reproductive isolation from the rest of the species. ►species

Substance Abuse: The proclivity is genetically controlled. Morphine preference has at least three known QTLs; alcoholism has also several QTLs. Some of these conditions may be associated with variations in the serotonin transporter. A genetic factor for the latter is linked to the human ALPC2 locus, controlling vulnerability to alcohol. The conditions leading to depression may generally affect substance abuse, some of the quantitative trait loci mentioned, however, do not appear to act globally. ►alcoholism, ►serotonin, ►QTL, ►steroid doping; Uhl GR et al 2001 *Am J Hum Genet* 69:1290.

Substantia Nigra: A site in the middle part of the brain (mesencephalon) with dark pigment deposits. The pigments are the products of the dopaminergic

neurons that control movement and coordination; dopamines are essential neurotransmitters. In Parkinson disease, the cells degenerate and cannot make sufficient amounts of the dopamine pigment. Somatic mutations (deletions) in the mitochondrial DNA are associated with respiratory deficiency and selective loss of neurons that are observed in aging and Parkinson disease (Bender A et al 2006 *Nature Genet* 38:515; Kraytsberg Y et al 2006 *Nature Genet* 38:518). ►Parkinson disease, ►neurotransmitter, ►aging, see Fig. S136.

Figure S136. Substantia nigra location in the brain

Substitution, Disomic: Two homologous chromosomes replaced by two others. ►alien substitution, ►inter-varietal substitution

Substitution Line: One of its chromosomes (or pair) is derived from a donor variety or species. ►alien substitution, ►intervarietal substitution

Substitution, Monosomic: One entire chromosome is substituted for another. ►substitution line

Substitution Mutation: When a base pair is replaced by another. The evolutionary mutation rate in the human X chromosome is lower than in the Y chromosome and the ratio is about 1.7 at the 95% confidence level according to one study based on molecular analysis (see Fig. S137). ►transition and transversion, ►base substitution, ►point mutation, ►Li-Fraumeni syndrome, ►SNIP, ►base sequences

Substoichiometric Shift: The mtDNA of some species undergoes rounds of unequal recombinations and, thus, generates mutations in this organelle and possibly also in the plastids. The organelle mutations are then maternally inherited. ►mutator genes, ►mitochondrial genetics

Figure S137. Base substitution mutations in the p53 gene in the noncancerous fibroblast cells in a family with the Li-Fraumeni syndrome. (1) Proband, (2) his brother, (3) their father and (4) a normal control. In codon 245 GGC→GAC mutations are evident in the two generations investigated. (Courtesy of Professor Esther H. Chang; see also Nature [Lond] 348: 747)

Substrate: The compound an enzyme can act on, or the culture medium for an organism, or a particular surface. ▶ [pseudosubstrate](#)

Substrate Adhesion Molecules (SAM): Bind as extracellular molecules to independent receptors on adhering cells.

Substrate Cycle: ▶ [futile cycle](#)

Substrate Induction: Enzyme synthesis is stimulated by the presence of the substrate of the enzyme. ▶ [lac operon](#), ▶ [substrate](#)

Substrate Ordering: The order of degradation—by multiubiquitination—of the cell cycle regulators by the anaphase-promoting complex (APC). (See Rape M et al 2006 Cell 124:89; ▶ [cell cycle](#), ▶ [APC](#), ▶ [ubiquitin](#)).

Subtelomeric Duplications: ▶ [telomeres](#)

Subtiligase: An enzyme capable of ligating esterified peptides in aqueous solutions.

Subtilisin: A protease enzyme that cuts at serine in the context Gly-Thr-Ser-Met-Ala-Ser; chymotrypsin also cuts at serine but within a different sequence. Subtilisin is translated as a pre-pro-polypeptide containing the IMC (intramolecular chaperon) sequence between the signal peptide and the mature enzyme. IMC is responsible for the folding of the final enzyme without being present in the functional subtilisin, which is a general scavenger molecule. ▶ [chymotrypsin](#), ▶ [scavenger molecules](#), ▶ [signal peptide](#)

Subtraction Genomic: ▶ [genomic subtraction](#)

Subtractive Cloning (driver excess hybridization): Provides information of genes selectively expressed in different tissues. A single-stranded RNA (or DNA,

the so-called tracer) is hybridized to another nucleic acid (the driver), which is present in the reaction mixture at least 10-fold in excess. Usually, from the tester RNA a cDNA is generated by the use of poly (dT) primers. Then from the single strand cDNA, double-strand DNA is generated with the aid of poly (dT) primer. The tester cDNA is mixed with an excess of driver cDNA and the cDNAs are allowed to reanneal after denaturation. The double-strand DNA is removed by adsorption to a hydroxyapatite column. The hybrids and the unhybridized driver are selectively removed (subtraction) and the remaining single-stranded, unhybridized tracer is further enriched by hydroxyapatite, biotinylation and selection by streptavidin, chemical cross-linking, RNase H and PCR. The process may be repeated until pure tracer-specific nucleic acid becomes available. This can then be used to screen a library for tracer-specificity. The procedure bears much similarity to c_0t or r_0t analysis. Hyperchromicity or digestibility by S1 nuclease can monitor the single-stranded molecules. The technique may provide information on the number or kind of genes expressed in specific tissues. ▶ [hydroxyapatite](#), ▶ [streptavidin](#), ▶ [genomic subtraction](#), ▶ [RFLP subtraction](#), ▶ [positive selection](#), ▶ c_0t , ▶ r_0t analysis, ▶ [S1 nuclease](#), ▶ [hyperchromicity](#), ▶ [tissue-specificity](#), ▶ [nucleic acid hybridization](#), ▶ [cascade hybridization](#), ▶ [subtractive hybridization](#), ▶ [normalization](#); Sagerström CG et al 1997 Annu Rev Biochem 66:751.

Subtractive Hybridization: ▶ [subtractive cloning](#)

Subtractive Suppression Hybridization (SSH): First subtracted cDNA libraries are generated. Then selective and/or suppressive cycles of PCR is combined with normalization and subtraction in

a single procedure. The normalization equalizes the abundance of cDNAs within the samples and the subtraction excludes the sequences common to the target and driver populations. The procedure is well suited for identification of disease, developmental or other differentially expressed genes. ▶PCR, ▶subtractive cloning; Diatchenko L et al 1999 Methods Enzymol 303:349; den Hollander AI et al 1999 Genomics 58:240; Nishizuka S et al 2001 Cancer Res 61:4536; selective transcriptome extraction: Li L et al 2005 Nucleic Acids Res 33:(16):e136.

Substrain: A line separated from another after 8–19 cycle of inbreeding or when a single colony is different from the rest of the strain of rodents. ▶subline, ▶inbred

Subunit Vaccine: Contains only a fragment of the antigenic protein, sufficient to stimulate an immune response. ▶vaccines, ▶antigen

Subunits of Enzymes (protomers): The polypeptides that make up the oligomeric proteins.

Subvital: Has reduced viability, yet has 50% chance to survive up to the reproductive period of the species. ▶sublethal

SUC2: Yeast invertase gene; it mediates glucose effect and may be suppressed by *ssn* (suppressor of *snf*). ▶SSN6, ▶SNF, ▶glucose effect

Succinate Dehydrogenase: A non-heme iron, inner mitochondrial dehydrogenase enzyme (subunits encoded at human chromosomes 11q23 and 1q21). It converts succinate to fumarate while flavin adenine dinucleotide serves as a H_2 acceptor. ▶phaeochromocytoma, ▶mitochondrial diseases in humans

Sucrose Gradient Centrifugation: ▶density gradient centrifugation

Sucrose Intolerance: ▶disaccharide intolerance

Sucrose Transporters: Deliver the photosynthetically produced sucrose within the plant body. ▶photosynthesis; Truernit E 2001 Curr Biol 11:R169.

Sudan Black: In microscopic use, it stains fatty tissues, wax, resins, cutins, etc., red.

Sudden Infant Death Syndrome (SID): Unexpected death of healthy, normal infants within the first year of life during sleep. It appears to be associated with a deficiency in the binding of the muscarinic cholinergic receptors of the brain resulting in accumulation of carbon dioxide or lack of oxygen in the blood. ▶muscarinic acetylcholine receptors

Sufficiency, Statistical: Indicates that all necessary information about a parameter has been obtained.

SUG1: An ATPase and activator of transcription; it can substitute in yeast for Trip1 and can interact with the transcriptional activation domain of GAL4 and herpes virus protein VP16. ▶ATPase, ▶transcriptional activator, ▶Trip1, ▶GAL4, ▶signal transduction

Sugar Beet (*Beta vulgaris*): $2n = 18$ (see Fig. S138). One of the greatest success stories of plant breeding. In the middle of the eighteenth century, the average sugar content of the plant was about 2%. This increased by the twentieth century to about 20%, and the sugar yield per hectare increased to about 4 metric tons. Some of the modern varieties have numerous agronomically important features (disease resistance, monogerm), and this is a rare plant where triploid varieties (besides bananas) are grown commercially. ▶banana, ▶monogerm seed

Figure S138. Sugar beet

Sugar Code: Hypothesized to involve proteoglycan modifications on the basis that heparan sulfate and chondroitin sulfate proteoglycans would control axon guidance. ▶heparan sulfate, ▶chondroitin sulfate, ▶axon guidance; Holt CE, Dickson BJ 2005 Neuron 46:169.

Sugarcane: (*Saccharum*, $x = 10$); its diploid forms are unknown and the cultivated varieties have high and variable number of chromosomes (*S. spontaneum* $2n = 36-128$, *S. robustum* $2n = 60-170$, *S. officinarum* $2n = 70-140$), including polyploids and aneuploids. The modern cultivated forms are natural hybrids of *S. spontaneum* \times *S. officinarum* (this hybrid is also called *S. barberi* in India and *S. sinense* in China). Genetic mapping requires DNA markers, which—unlike the gene markers—can be studied despite the complex chromosomal situations. It is the most important source of saccharose or common sugar. ▶sugar beet

Sugars: Mono- and oligosaccharides, components of polysaccharides and have important role in nutrition, and in complexes of critical significance in immunology, cancer, other diseases, several pigments, etc. Database for chemistry, classification, structure,

physiological role: <http://www.glycosciences.de/sweetdb/index.php>.

Suicidal Antibody: The antibody is equipped with a targeting signal that can direct it to a degradative cellular compartment (e.g., lysosome, proteasome) where the bound antigen is destroyed. ►[lysosome](#), ►[proteasome](#); Larbig D et al 1979 Pharmacology 18:1; Hsu KF et al 2001 Gene Ther 8(5):376.

Suicidal Behavior: Appears to have a familial component. The suspected association between tryptophan hydroxylase and suicidal behavior is not supported by recent analysis (Lalovic A, Turecki G 2002 Am J Med Genet 114:533).

Suicide Inhibitor: A molecule that inhibits enzyme action after the enzyme acted upon it. In the original form, it is only a weak inhibitor but after reacting with the enzyme it binds to it irreversibly and becomes a very potent inhibitor. Allopurinol, fluorouracil are such molecules. ►[allopurinol](#), ►[regulation of enzyme activity](#)

Suicide Mutagen: Uses a ^{32}P -labeled or other radioactive nucleotide that is incorporated into the genetic material and causes mutation by localized radiation. ►[magic bullet](#)

Suicide Vector: Delivers a transposon into the host cells in which the vector itself cannot replicate but the transposon can be maintained and used for transposon mutagenesis. Additional use involves the delivery of Herpes simplex virus thymidine kinase gene (HSV-TK) and administering ganciclovir or acyclovir. The HSV-TK is about three orders of magnitude more effective than the cellular TK in phosphorylating these DNA base analogs and thus blocking DNA synthesis. The phosphorylated ganciclovir is also impaired in moving through cell membranes and has longer-lasting local effects. Eventually some ganciclovir resistance may develop. The delivery of the gene for cytosine deaminase (CD) and the compound 5-fluorocytosine may produce within the target 5-fluorouracil, a DNA inhibitor. Xanthine-guanine phosphoribosyltransferase (XGPRT) may make the tumor cells more sensitive to 6-thioxanthene. P450-2B1 gene encoding a cytochrome, converts cyclophosphamide into the toxic phosphoramidate mustard. The *deoD* bacterial gene (purine-nucleoside phosphorylase) converts 6-methylpurine deoxyribonucleoside into the deleterious 6-methylpurine. The bacterial nitroreductases convert the relatively non-toxic monofunctional N-chloroethylamine-derivative, C1954, into 10^4 times more active bifunctional alkylating agent. Employing HSV-TK, CD and XGPRT to the same tumor, three different

transgenic cell populations, a mosaic may result. Theoretically, this could be used in a preventive program in putative cancer-prone cases. If the HSV-TK cells would become cancerous, ganciclovir would eliminate that cell subpopulation and the healthy tissues carrying the CD and XGPRT can take over as a prophylactic measure. Unfortunately, this mosaic approach has serious limitations at this time. Targeting a foreign antigen (e.g., HLA-B7 protein) to the cancer cells may stimulate the immune system of the host and kill the tumor cells. The immune system may be stimulated by transformation with cytokine genes. ►[transposon mutagenesis](#), ►[ganciclovir](#), ►[gene therapy](#), ►[cancer gene therapy](#), ►[immunotherapy adoptive](#), ►[cytokines](#), ►[HLA](#), ►[bystander effect](#), ►[cytosine deaminase](#), ►[thymidine kinase](#); Takamatsu D et al 2001 Plasmid 46:140.

Sulfatase Deficiency: ►[mucosulfatidosis](#)

Sulfhydryl Group: —SH, and when two are joined the linkage is a disulfide bond. Sulfhydryl compounds, such as cysteine and cysteamine are protectors against ionizing radiation. ►[thiol](#), ►[cysteine](#), ►[cysteamine](#)

Sulfocysteinuria: A deficiency of sulfite oxidase. Restricted intake of sulfur amino acids in the diet greatly reduces sulfocysteine and thiosulfate in the urine and improves conditions.

Sulfolobus (Archaea): genomes database: <http://www.sulfolobus.org>.

Sulfonylurea: A group of compounds that stimulate insulin production by regulating insulin secretion and lower blood sugar level; it is used to treat patients with non-insulin dependent diabetes. These drugs interact with the sulfonylurea receptor of pancreatic β cells and inhibit the conductance of ATP-dependent K^+ ion channels. Reduction of potassium exit activates the inward rectifying Ca^{2+} channels and promotes exocytosis. Sulfonylureas are inhibitors of the acetolactate synthase enzyme and there are also sulfonylurea herbicides. ►[ion channels](#), ►[diabetes](#), ►[herbicides](#)

Sulfur Mustard: See Fig. S139 where Al is an alkyl group. If the two alkyl groups are chlorinated (Cl) the compound is called bifunctional. If only one alkyl group is chlorinated, the compound is monofunctional. ►[nitrogen mustard](#), ►[alkylating agents](#); Michaelson S 2000 Chem Biol Interact 125:1.

Figure S139. Sulfur mustard

Sulfurylase: Catalyzes the reaction $\text{ATP}^{3-} + \text{SO}_4^{2-} \rightarrow$ adenylyl sulfate (adenosine-5'-phosphosulfate, $\text{C}_{10}\text{H}_{14}\text{N}_5\text{O}_{10}\text{PS}$).

Sulston Score: Used for comparative microsynteny analysis. It displays matching status of fingerprints of a chosen genomic clone and its matching sequences in others by a given probability of coincidence and a given tolerance. The analysis permits physical mapping of genomes. The scores may vary from 04 to 38 and the lower is more stringent. (See Sulston J et al 1988 Comput Appl Biosci 4:125).

Summary Statistic: Defines characteristics of a diverse population by the mean and variances. ▶mean, ▶variance

Sum of Squares: The sum of the squared deviations from their mean of the observations; it is used in statistical procedures to estimate differences. ▶analysis of variance, ▶intraclass correlation

SUMO (small ubiquitin-like modifier, 2q32.2-q33): Ubiquitin-like carrier proteins (11 kDa). Sumos are conjugated to a variety of proteins (RanGAP1-Ubc9-Nup358) and seem to be involved in multiple functions such as cell cycle progression, DNA repair, spontaneous mutation, heterochromatin stabilization and counteract recombination events at damaged replication forks, etc. Histone sumoylation may repress transcription. ▶UBL, ▶monoubiquitin, ▶sentrin, ▶PIC, ▶IκB, ▶IKK, ▶RAN, ▶Ubc9, ▶nuclear pores, ▶Huntington's chorea, ▶NF-κB; Melchior F 2000 Annu Rev Cell Dev Biol 16:591; Müller S et al 2001 Nature Rev Mol Cell Biol 2:202; Shiio Y, Eisenman RN 2003 Proc Natl Acad Sci USA 100:13225; Reverter D, Lima CD 2005 Nature [Lond] 435:687; crystal structure of thymine DNA glycosylase-SUMO: Baba D et al 2005 Nature [Lond] 435:979; heterochromatin: Shin JA et al 2005 Mol Cell 19:817; sumoylation site server: <http://bioinformatics.lcd-ustc.org/sumosp/>.

Sunburn: Sunburn (UV) causes keratoses in about 60% of the cases. The p53 gene may suffer mutation(s), mainly C→T transitions. These p53 mutant cells, after clonal propagation, may develop into squamous cell skin cancer (SCC). In over 90% of the SCC cells, the p53 gene is mutant. The increased melanin production involved with ultraviolet light exposure may be correlated with the DNA repair system. ▶p53, ▶keratoses, ▶DNA repair, ▶ultraviolet light, ▶pigmentation in animals, ▶melanoma

Sunds: ▶Brugada syndrome

Sunflower (*Helianthus*): An oil crop with about 70 xenogamous species, $2n = 2x = 34$. (See Burke JM et al 2002 Genetics 161:1257).

Sun-Red Maize: Develops anthocyanin pigment when the tissues are exposed to sunshine (e.g., through a stencil) (see Fig. S140).

Figure S140. Sun-red maize ear

SUP35: ▶prion

supB: Ochre/amber suppressor; it inserts glutamine.

supC: A suppressor mutation for amber (5'-UAG-3') and ochre (5'-U3') chain-terminator codons. The mutation causes a base substitution in the anticodon of tyrosine tRNA (5'-GUA-3') and it changes to 5'-UUA-3' that can recognize both the ochre and amber codons as if they were tyrosine codons. Note: pairing is 5'-3' and 3'-5'. For the recognition of the former, wobbling is required. ▶suppressor, ▶wobbling, ▶anticodon, ▶ochre, ▶amber

supD: An amber suppressor mutation that reads the amber (5'-UAG-3') chain termination codon as if it would be a serine (5'-UCG-3') codon because the normal serine tRNA anticodon (5'-CGA-3') mutates to (5'-CUA-3'), therefore, instead of terminating translation, a serine is inserted into the amino acid chain. (Remember, the pairing is antiparallel). ▶suppressor, ▶anticodon

supE: An amber-suppressor mutation that reads the chain-termination codon 5'-UAG-3' (amber codon) in the mRNA as if it would be a glutamine codon (5'-CAG-3') because the glutamine tRNA anticodon mutates to 5'-CUA-3' from the 5'-CUG-3'. As a consequence, the translation proceeds and a glutamine is inserted at the site where in the presence of an amber codon in the mRNA the translation would have terminated. (Note: the pairing is antiparallel).

supF: Amber suppressor; it inserts tyrosine.

Superantigen: Native bacterial and viral proteins that can bind directly (without breaking up into smaller peptides) to MHC class II molecules on antigen-presenting cells. The variable regions of T cell receptor β chains thus activate more T cells against, e.g., enterotoxins of *Staphylococci*—causing toxic shock syndrome or food poisoning—than normal antigens. Cellular superantigens are likely to be responsible for such diseases as diabetes mellitus. ▶MHC, ▶TCR, ▶enterotoxin, ▶toxic shock

syndrome, ►diabetes mellitus, ►antigen, ►endogenous virus; Muller-Alouf H et al 2001 Toxicon 39:1691; Alam SM, Gascoigne NR 2003 Methods Mol Biol 214:65.

Superchiasmatic Nucleus: A region near the optical center of the hypothalamus in the brain controlling circadian signals. ►brain, ►circadian rhythm

Supercoiled DNA: May assume the *positive supercoiled* structure by twists in the same direction as the original, generally (right handed) coiling of the double helix, or it may be twisted in the opposite direction, *negative supercoiling*. Negative supercoiling (Z DNA) may be required for replication and transcription (see Fig. S141).

Figure S141. Supercoiled DNA plasmid of *Streptococcus lactis*. (Courtesy of Dr. Claude F. Garon)

The superhelical density expresses the superhelical turns per 10 bp and it is about 0.06 in cells as well as in virions. Loss of positive supercoiling may be lethal. Localized negative supercoiling may be lethal. Localized negative supercoiling is essential for gene expression, replication and many other functions of the DNA. ►DNA replication prokaryotes, ►transcription, ►Z DNA, ►packing ratio, ►linking number; Holmes VF, Cozarelli NR 2000 Proc Natl Acad Sci 97:1322.

Superdominance: Same as overdominance or monogenic heterosis. ►hybrid vigor, ►overdominance

Superfamily of Genes: A group of genes that are structurally related and may have descended from common ancestors although their present function may be different. (See <http://supfam.mrc-lmb.cam.ac.uk/SUPERFAMILY/index.html>).

Superfamily of Proteins: Evolutionarily related proteins. (See <http://cathwww.biochem.ucl.ac.uk/latest/index.html>).

Superfemale (metafemale): *Drosophila*, trisomic for the X-chromosome (XXX) but disomic for the autosomes; she is sterile. ►aneuploidy, ►supermale *Drosophila*

Superfetation: Due to an apparently rare autosomal dominant gene ovulation may continue after implantation of the fertilized egg and an unusual type of twinning results. In animals, when a female may mate repeatedly with several males, the same litter may become multipaternal. Human dizygotic twins may also be of different paternity when during the receptive period the female had intercourse with two different males. ►twinning, ►multipaternal litter; Fontana J, Monif GR 1970 Obstet Gynecol 35:585.

Supergenes: Linked clusters of genes that are usually inherited as a block because inversion(s) prevent(s) the survival of the recombinants for the clusters and thus have evolutionary and applied significance in plant and animal breeding. Supergenes may be adaptively linked polymorphic loci.

Superinfection: A bacterium is infected by another phage. This is generally not possible in a lysogenic bacterium because of immunity, i.e., the superinfecting phage cannot enter a vegetative cycle within the lysogen. Infection by two T even phages may fail in such an attempt by “superinfection breakdown.” Some higher organisms may be infected by parasites of different genotypes. The number of clones of the parasites may not increase with the progression of the disease indicating competition among the superinfecting strains (e.g., *Plasmodium*) ►immunity, ►phage, ►Plasmodium; Hayes W 1965 The Genetics of Bacteria and their Viruses. Wiley, New York; Vogt B et al 2001 Hum Gene Ther 12(4):359.

Supermale Asparagus: Can be obtained by regenerating and diploidizing plants obtained from Y chromosomal microspores or pollen by the techniques of cell culture. Thus, their chromosomal constitution is 18 autosomes + YY. These plants are commercially advantageous because of the higher yield of the edible spears. ►YY Asparagus

Supermale Drosophila: Has 1 X and 3 sets of autosomes, i.e., the fly is monosomic for X but he is trisomic for all the autosomes; he is sterile. ►superfemale, ►sex determination

Superman: A homeotic mutation in *Arabidopsis* resulting in excessive development of the androecium at the expense of other flower parts. The DNA base sequences are the same as in the wild type but the mutation evokes methylation. ►flower differentiation, ►androecium; Koshimoto N et al 2001 Plant Mol Biol

46:171; Cao X, Jacobsen SE 2002 *Curr Biol* 12:1138; Dathan N et al 2002 *Nucleic Acids Res* 30:4945.

Super-Mendelian Inheritance: The transmission of one of the alleles in a diploid is preferential because of the advantage of a gene at meiosis or post-meiotic steps of gametogenesis. This advantage may not be due an intrinsic superiority of the allele. Homing endonuclease genes (HEG) may be preferentially transmitted horizontally, but may or may not be propagated at a selective advantage. ▶homing endonuclease, ▶segregation distorter, ▶meiotic drive, ▶preferential segregation; Goddard MR, Burt A 1999 *Proc Natl Acad Sci USA* 96:13880.

Supermutagen: An efficient mutagen that causes primarily point mutations without inducing frequent chromosomal defects. ▶point mutation, ▶ethyl-methane sulfonate, ▶nitrosoguanidine

Supermutation: ▶hypermutation, ▶somatic hypermutation, ▶antibody gene switching

Supernatant: The non-sedimented fraction after centrifugation of a suspension or in general, any floating fraction derived of a mixture.

Supernatural: ▶paranormal

Supernumerary Chromosome: ▶B chromosome, ▶cat eye syndrome

Supernumerary Marker Chromosome: Rare ($\sim 3 \times 10^{-4}$) abnormal chromosomes with internal duplications and deletions. The majority ($\sim 60\%$) involves two inverted copies of the short arm, centromere and the proximal segment of the long arm of human chromosome 15 (SMC[15]). The majority of the latter are dicentric but one of the centromeres is inactive (pseudocentromeric 15). ▶chromosomal rearrangements; Roberts SE et al 2003 *Am J Hum Genet* 73:1061.

S

Superoperon: A regulatory complex tied together, e.g., photoreceptor pigment synthesis and photosynthesis. ▶operon, ▶überoperon, ▶supraoperon

Superovulation: By injection of gonadotropic hormones (into mice), the number of eggs produced may increase several fold. Fertilization follows after about 13 h and the eggs can be surgically collected to study, in vitro, the preimplantation development. Hormonal treatment may cause superovulation also in usually monoparous animals too. ▶twinning

Superoxide ($O_2^{\bullet-}$): A highly reactive species of oxygen. In the hypersensitivity reaction defense mechanism, it appears to play an important role along with nitric oxide. ▶nitric oxide, ▶hypersensitivity reaction,

▶SOD, ▶hydrogen peroxide, ▶ROS, ▶Fenton reaction, ▶peroxynitrite, ▶peroxides

Superoxide Dismutase (SOD): Catalyzes the reaction $2O_2 + 2H^+ \rightarrow O_2 + H_2O_2$ and thus participates in the detoxification of the highly reactive (mutagenic) superoxide radical $O_2^{\bullet-}$. These enzymes are the main detoxificants of the free radicals. SOD overexpression confers resistance to ionizing radiation under aerobic conditions. There are three isozymes of SOD: the cytosolic SOD-1 (human chromosome 21q22.1, the mitochondrial SOD-2 [6q25.3] and the extracellular SOD-3 [4pter-q21]). In SOD deficiency, cardiomyopathy, brain damage, mitochondrial defects, Lou Gehrig's disease and precocious aging may result. A non-peptidyl manganese complex with bis (cyclohexylpyridine)-substituted macrocyclic ligand may mimic SOD activity. Inhibition of SOD enzymes may trigger suicide of leukemia cells, which have a higher rate of oxidative metabolism. Cell suicide may also occur when the level of hydrogen peroxide is high or when the latter is converted to hydroxyl radicals in a Fe^{2+} dependent process. Using the cytosolic SOD gene in an adenoviral vector may provide protection against ROS injury. ▶amyotrophic lateral sclerosis, ▶granulomatous disease, ▶cardiomyopathies, ▶aging, ▶ROS, ▶host-pathogen relationship, ▶oxidative stress, ▶AMPA; Fridovich I 1975 *Annu Rev Biochem* 44:147; Danel C et al 1998 *Hum Gene Ther* 9:1487.

Superparamagnetic Scale Particles: ▶magnetic relaxation switches, ▶magnetic targeting

Super-Repressed: Bacterial operon cannot respond to inducer. ▶repression, ▶inducer

Supershift: ▶gel retardation assays

Supersuppressor: A dominant suppressor acting on more than one allele or even on different gene loci. ▶suppressor; Gerlach WL 1976 *Mol Gen Genet* 144:213.

Supervillin: ▶androgen receptor

Supervised Learning: Finding shared patterns or motifs common to all "positive" sequences and absent from all "negative" ones in a curated way. ▶motif, ▶unsupervised learning, ▶curated; Moler EJ et al 2000 *Physiol Genomics* 2(2):109.

Supervital: Fitness exceeds that of the standard (wild) type.

supF: An amber-suppressor mutation in $tRNA^{Tyr}$ that recognizes the chain-termination codon (5'-UAG-3') as if it would be a tyrosine codon (5'-UAC-3' or

5'-UAU-3') because a mutation at the anticodon sequence in the tyrosine tRNA changes the 5'-GUA-3' into a 5'-CUA-3' and thus the tyrosine tRNA inserts a tyrosine into the growing peptide chain where translation would have been terminated. ►[suppressor tRNA](#), ►[πVX](#).

supG: Suppressor mutation for both amber (5'-UAG-3') and ochre (5'-UAA-3') chain termination codons, by a base substitution mutation in the anticodon of lysine tRNA from (5'-UUU-3') to 5'-UUA-3' that can recognize the amber and ochre codons in the mRNA, as if they would be lysine (5'-AAA-3' or 5'-AAG-3') codons and thus inserting in the peptide chain a lysine rather than discontinuing translation. (Note: the pairing is antiparallel).

Support: A statistical concept it is synonymous with log likelihood. ►[likelihood](#)

Support Vector Machine (SVM): A computer program based on the principle of supervised learning techniques. It uses a training set to determine which data should be clustered a priori. The operations start with a set of genes that are already known to have common function, e.g., genes that encode ribosomal proteins. It picks another set of genes that are not members of the functional group specified. These two sets form the training examples and the genes are marked positive in case they fall in the specified functional class or negative if they are not. The SVM thus learns from the two groups how to discriminate and classify any “unknown” on the basis of function. This procedure can classify genes based on microarray hybridization data and identify functional clusters genome-wide. ►[microarray hybridization](#), ►[machine learning](#), ►[supervised learning](#), ►[cluster analysis](#); Brown MPS et al 2000 Proc Natl Acad Sci USA 97:262; Hua S, Sun Z 2001 Bioinformatics 17(8):721; Cristianini N, Shawe-Taylor J 2000 An Introduction to Support Vector Machines and Other Kernel-Based Learning Methods. Cambridge University Press, New York.

Supportive Counseling: To alleviate the psychological problems involved with the discovery of hereditary disorders and birth defects in families. ►[counseling genetic](#)

Suprachiasmatic Nucleus: A small site in the hypothalamus above the optic region controlling rhythmic function of the body and memory of all vertebrates. ►[brain human](#)

Supramolecular/Supermolecular: Literally means beyond molecular, but it is also used for structures assembled from molecules held together by bonds weaker than those within molecules are. The number

of molecules, how they are connected, and the way they are oriented relative to each other, characterizes the system structurally. Supermolecular structure is important for understanding how cells function. (See Turro NJ 2005 Proc Natl Acad Sci USA 102:10765).

Supraoperon: A region of the prokaryotic genome where operons of similar function are located, e.g., in the aromatic (*aro*) amino acid pathway including tryptophan (*trp*) and histidine (*his*): ►[operon](#), ►[überoperon](#), ►[superoperon](#); Berka RM et al 2003 Proc Natl Acad Sci USA 100:5682.

Supravalvar Aortic Stenosis (SVAS): A human chromosome 7q11 dominant mutation in an elastin gene with a prevalence of about 5×10^{-5} causing obstruction of the aortic blood vessels. The basic defect is due to a deficiency of elastin. It is pleiotropic and part of the Williams syndrome. ►[coarctation of the aorta](#), ►[cardiovascular diseases](#), ►[William's syndrome](#), ►[elastin](#)

Suppressor, Bacterial: Protein product of the bacterial regulator gene (e.g., *i* in the *Lac* operon) that when associated with the operator prevents transcription. ►[Lac operon](#), ►[ara operon](#)

Suppressor, Extragenic: The suppressor mutation is outside the boundary of the suppressed gene. ►[suppressor tRNA](#), ►[second-site suppressor](#), ►[second site reversion](#)

Suppressor Gene: Restores function lost by a mutation without causing a mutation at the site suppressed. The suppressor can be intragenic (within the cistron but also at another site) or at any other locus, e.g., in the signal transduction pathway. The suppressor may act by reducing and also by overexpression of a gene product. ►[suppressor extragenic](#), ►[suppressor intragenic](#), ►[suppressor informational](#), ►[frameshift](#), ►[mutation in organelle DNA](#)

Suppressor, Haplo: Dominant suppressor that can act in a single dose.

Suppressor, Informational: Interferes with the expression of another gene at the level of translation by affecting either tRNAs or ribosomes or peptide elongation factors.

Suppressor, Intragenic: The suppressor site is within the gene where suppression takes place. ►[frameshift suppressor](#)

Suppressor Mutation: ►[suppressor gene](#), ►[sup](#), ►[suppressor tRNA](#), ►[suppressor RNA](#), ►[frameshift suppressor](#), ►[mitochondrial suppressor](#)

Suppressor RNA (sRNA): Prevents translation of a mRNA by partial base pairing with a specific

sequence of the target. Two 22 and 40 nucleotide long tracts of the *lin-4* transcripts control the translation of gene *lin-14*. The latter is an early expressed nuclear protein in *Caenorhabditis* but its expression is blocked during later stages by the *lin-4* RNA that itself is not operating through a protein. Several other genes are subject to RNA suppressors in other organisms. The mechanism of this suppression seems to be different from that of the suppressor tRNA. ▶**suppressor tRNA**, ▶**suppressor gene**, ▶**antisense RNA**, ▶**antisense DNA**, ▶**RNAi**, ▶**repressor**; Olsthoorn RC et al 2004 RNA 10:1702.

Suppressor, Second Site: A suppressor outside the boundary of the locus but usually within the same chromosome. ▶**suppressor gene**, ▶**second site reversion**

Suppressor Selection Gene Fusion Vector: Carries nonsense codon(s) in the structural gene and can be expressed only if the target genome carries nonsense suppressors. ▶**vectors gene fusion**, ▶**transcriptional gene fusion vector**

Suppressor T Cell: Can suppress antigen-specific and allospecific T cell proliferation by competing for the surface of antigen-presenting cells. ▶**T cell**, ▶**allospecific**; Maloy KJ, Powrie F 2001 Nature Immunol 2:816.

Suppressor tRNA: Makes the translation of nonsense or of missense codons in the original, normal sense possible because a mutation in the anticodon of the tRNA recognizes the complementary sequence in the codon but its specificity resides in the tRNA molecule (see Fig. S142). Exceptions are possible, however. In the anticodon 5'-CCA-3' of the tryptophan codon (5'-UGG-3') is not mutant yet it may deliver to the opal position a tryptophan if at position 24 of the D loop of the tryptophan tRNA a guanine is replaced by an adenine. Similarly, if in the GGG codon of glycine another G base is inserted by a frameshift mutagen but subsequently, in its anticodon (CCC) an extra C is inserted then the tRNA may read the four bases normally as a glycine codon rather than nonsense. Beyond the codon-anticodon binding, mutation elsewhere in tRNA^{Trp} can effect the correct decoding (Cochella L, Green R 2005 Science 308:1178). ▶**tRNA**, ▶**Hirsh suppressor**, ▶**code genetic**, ▶**mutation in organelle DNA**, ▶**phenotypic reversion**, ▶**translation in vitro**; Smith JD et al 1966 Cold Spring Harb Symp Quant Biol 31:479; Murgola EJ 1985 Annu Rev Genet 19:57; Beier H, Grimm M 2001 Nucleic Acids Res 29:4767.

Figure S142. Suppressor tRNA

supU: A suppressor of the opal (5'-UGA-3') chain terminator codon with an anticodon sequence of 5'-UCA-3'. The mutation changes the anticodon of the tryptophan tRNA from 5'-UCA-3' to 5'-CCA-3' and that permits the insertion of a tryptophan residue into the polypeptide chain where it would have been terminated without the suppressor mutation (codon-anticodon recognition is antiparallel). This suppressor mutation is unusual because it recognizes both the tryptophan codon (5'-UGG-3') and the opal suppressor codon, i.e., its action is ambivalent.

SurA: Periplasmic parvulin type peptidyl-prolyl isomerase involved in chaperoning outer membrane proteins. ▶**peptidyl-prolyl isomerase**, ▶**parvulin**, ▶**periplasma**

Surface Antigen: Generally, glycoprotein molecules on the cell surface that determine the identity of the cells for immunological recognition. The display of surface antigens is regulated at the level of transcription. ▶**VSA**, ▶**antigen**, ▶**Trypanosomas**, ▶**Borrelia**

Surface Plasmon Resonance (SPR): Incoming light, in a certain angle, hits a hydrophilic dextran layer covered gold surface. The interacting molecule is immobilized on this surface. As the molecule injected binds to this surface the refractive index of the medium is increased and the change in the angle at which the intensity change occurs is measured in resonance units. The size of the macromolecule is positively correlated with the response. This analysis has numerous biological applications for the determination of protein-protein interactions such as antibody affinities, epitope, growth factor, signal transducing molecule, receptor, ligand binding, etc. ▶**biosensors**, ▶**microcalorimetry**, ▶**immunoprecipitation**; Heaton RJ et al 2001 Proc Natl Acad Sci USA 98:3701.

Surfactant: Common surfactants are soaps and detergents. In gene therapy, different surfactants such as perfluorochemical liquids, phospholipids may facilitate gene delivery to pulmonary tissues.

Surfection: A procedure to transfer genes to cells layered of the surface of polyethylenimine/collagen-coated wells. It can deliver multiple plasmids into cells at large-scale arrays. The procedure can assay RNAi-mediated silencing, live-cell imaging and cell-based drug screening. ▶RNAi; Chang F-H et al 2004 *Nucleic Acids Res* 32(3):e33.

Surrogate Chains (ΨL, ΨH): Of immunoglobulins are found in the progenitor (pro-) B lymphocytes. In the human and mouse fetal liver and adult bone marrow an 18 kDa protein with (~45%) homology to the variable regions of the κ, λ and heavy chains and a 22 kDa protein with ~70% homology to the constant region of the λ chain have been found. The synthesis of these proteins (ΨL) ceases after the IgM chains appear on the lymphocyte surface. They participate in the formation of the B cell receptor with other immunoglobulins and a short μ chain containing only the N-terminal D(J)C sequences. The ΨL light chains are associated with a complex of 130 kDa/35–65 kDa glycoproteins (ΨH) and together make the surrogate receptors. ▶immunoglobulins, ▶B lymphocytes, ▶immune system; Meffre E et al 2001 *J Immunol* 167:2151.

Surrogate Genetics: ▶reversed genetics

Surrogate Mother: A female who carries to term a baby for another couple. She may actually contribute the egg or may just be a gestational carrier of a fertilized egg and has no genetic share in the offspring. In either case, moral, ethical, psychological and legal problems must be pondered before this method of child bearing is chosen. Civil law generally keeps the maternal right of the gestational mother despite any contractual agreement contrary to natural parenthood. In case, however, the gestational mother is not the donor of the ovum, the maternal right pertains to the biological ovum donor. Obviously, there are serious ethical problems here beyond the principles of genetics. The society must protect the best interest of the child. ▶oocyte donation, ▶ART, ▶paternity testing

Surveillance, mRNA: A mechanism of quality control for the elimination of defective proteins. (See Hilleren P et al 1999 *Annu Rev Genet* 33:229; ▶immunological surveillance).

Survey Sequencing: Covers only 1x-2x of the genome, providing information on 60–80% of the sequences in a fragmented form, compared with complete sequencing that employs 6x-8x coverage. It is

a temporary compromise mandated by monetary, physical and manpower limitations. It still provides substantial information because several other genomes with homologies supplement and complement the missing information. (See Hitte C et al 2005 *Nature Rev Genet* 6:643).

Survival: The total survival probability per genetic damage is expressed by the equation:

$$S(\rho, \partial) = \sum_{h=0}^{h=\partial} P(\rho, h, \partial!)$$

where ρ = hit probability, ∂ = VD, V = total cell volume, D = density of the active events [dose], P = likelihood of survival. (See more in Alpen EL 1998 *Radiation Biophysics*. Academic Press; ▶target theory, ▶neutral mutation, ▶beneficial mutation, ▶cost of evolution, ▶genetic load, ▶fitness)

Survival Factors: Interfere with apoptosis. The balance between survival and apoptosis is very complex and a large number of proteins and ligands are involved through different pathways. (See Fig. S143, ▶apoptosis, ▶BAD, ▶survivin)

Survival Estimator: ▶Kaplan-Meier estimator

Survival of the Fittest: ▶fitness, ▶neo-Darwinism, ▶social engineering, ▶social Darwinism

Survival Phenotype: Under poor nutritional condition the fetus develops a lean body, undersized visceral organs, fewer muscle cells, undersized nephrons and liver. Because of the maternal nutritional deficiency, the promoters of many genes remain unmethylated in the early embryo, resulting in altered phenotype persisting into adulthood. After birth, they may gain more weight when food becomes available and may become diabetic. ▶nephron, ▶diabetes; Gluckman P, Hanson M 2005 *The fetal matrix: Evolution, development and disease*. Cambridge University Press.

Survivin: An inhibitory protein (16.5 K) of caspases that are activated by cytochrome c. It is antiapoptotic. Survivin is expressed as a passenger protein at the G2—mitosis phases of the cell cycle and it is associated with the microtubules of the mitotic spindle. Apoptosis may be caused by the disruption of this association. Overexpression of survivin may lead to cancer. Disruption of survivin action may reduce melanoma growth. Survivin is essential for the development of erythroid cells; but overexpression of survivin interfered with megakaryocyte development but did not affected erythroid cells (Gurbuxani S et al 2005 *Proc Natl Acad Sci USA* 102:11480). The *survivin* gene promoter contains several Sp1 canonical, Sp1-like, and p53-binding elements, suggesting participation of the Sp1

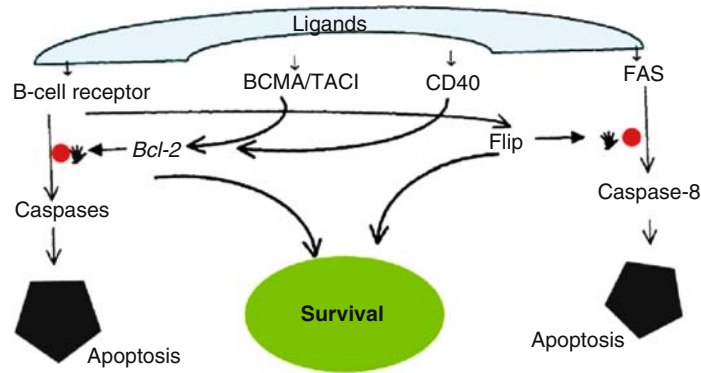

Figure S143. Survival factors

transcription factor and/or p53 in gene regulation. Furthermore, *survivin* transcription is down-regulated by the DNA-damaging agent doxorubicin, which mediates p53 induction in acute lymphoblastic leukemia (Estève P-O et al 2007 J Biol Chem 282:2615). ▶apoptosis, ▶cell cycle, ▶spindle, ▶survival factor, ▶passenger protein, ▶Stat, ▶megakaryocyte, ▶erythrocyte, ▶p53, ▶doxorubicin, ▶leukemia; Wheatley SP et al 2001 Curr Biol 11:886; Hoffman WH et al 2002 J Biol Chem 277:3247; Altieri D 2003 Nature Rev Cancer 3:46.

Suspension Culture: The cells are grown in liquid nutrient medium.

Suspensor: A line of cells through which the plant embryo is nourished by the maternal tissues. In general, anatomy ligaments may be called suspensors.

Sutent: ▶Gleevec

Suture: A junction of various solid animal and plant tissues.

Su(var): Suppressor of variegation. ▶heterochromatin; Rudolph T et al 2007 Mol Cell 26:103; Haynes KA et al 2007 Genetics 175:1539.

SUV39H1 (Clr): ▶histone methyltransferases

Sv: ▶Sievert

SV2s: Glycosylated transmembrane proteins, homologous to prokaryotic and eukaryotic transporters. ▶transporters

SV40 Tag: Simian virus 40 large T antigen. ▶Simian virus 40

SV40 Vectors: SV40 plasmids (vectors) can be packaged only if their DNA is within the range of 3900 to 5300 bp. Since these small genomes do not have much dispensable DNA, it is almost impossible to construct a functional vector with any added genes

to it. Fortunately, functions provided by helper DNA molecules might help to overcome these problems. Simian Virus 40 cannot replicate autonomously if the replicational origin (*ori*) is defective, yet it can integrate into chromosomal locations of green monkey cells and can then be replicated along the chromosomal DNA (such a cell is COS [cell origin simian virus]). Also, since the early genic region is normal (▶Simian Virus 40 for structure), it may produce the T antigen within the cell. If such a cell is transformed by another SV40 vector in what the viral early gene region was replaced by a foreign piece of DNA, the COS cell may act as a helper and replicate multiple copies of the second, the engineered SV40 DNA. Since the late gene region of this plasmid is normal, the viral coat proteins can be synthesized within the cell. The availability of the coat proteins permits the packaging of the engineered SV40 DNA into capsids.

The virions so obtained can be used to infect other mammalian cells where the passenger DNA can be transcribed and translated and the foreign protein can be processed. The transformed cell thus can acquire a new function. Also, an SV40 plasmid can be constructed with insertion into the late gene cluster, a foreign gene with a desired function. This plasmid can then use inactivated (deleted) early genes but with a good *ori* site. Upon coinfection of a mammalian cell with these two plasmids, the SV40 plasmids can replicate to multiple copies and the inserted foreign gene can be expressed. Also, it is feasible to insert into a prokaryotic pBR322 plasmid the *ori* region of SV40 and another piece of DNA including all the necessary parts of a foreign gene. When this plasmid is transfected into a COS cell, the passenger gene can be transcribed, translated and processed thanks to the multiple copies replicated within this mammalian cell. With the assistance of SV40 based constructs, mammalian and other genes can be shuttled between mammalian and bacterial cells.

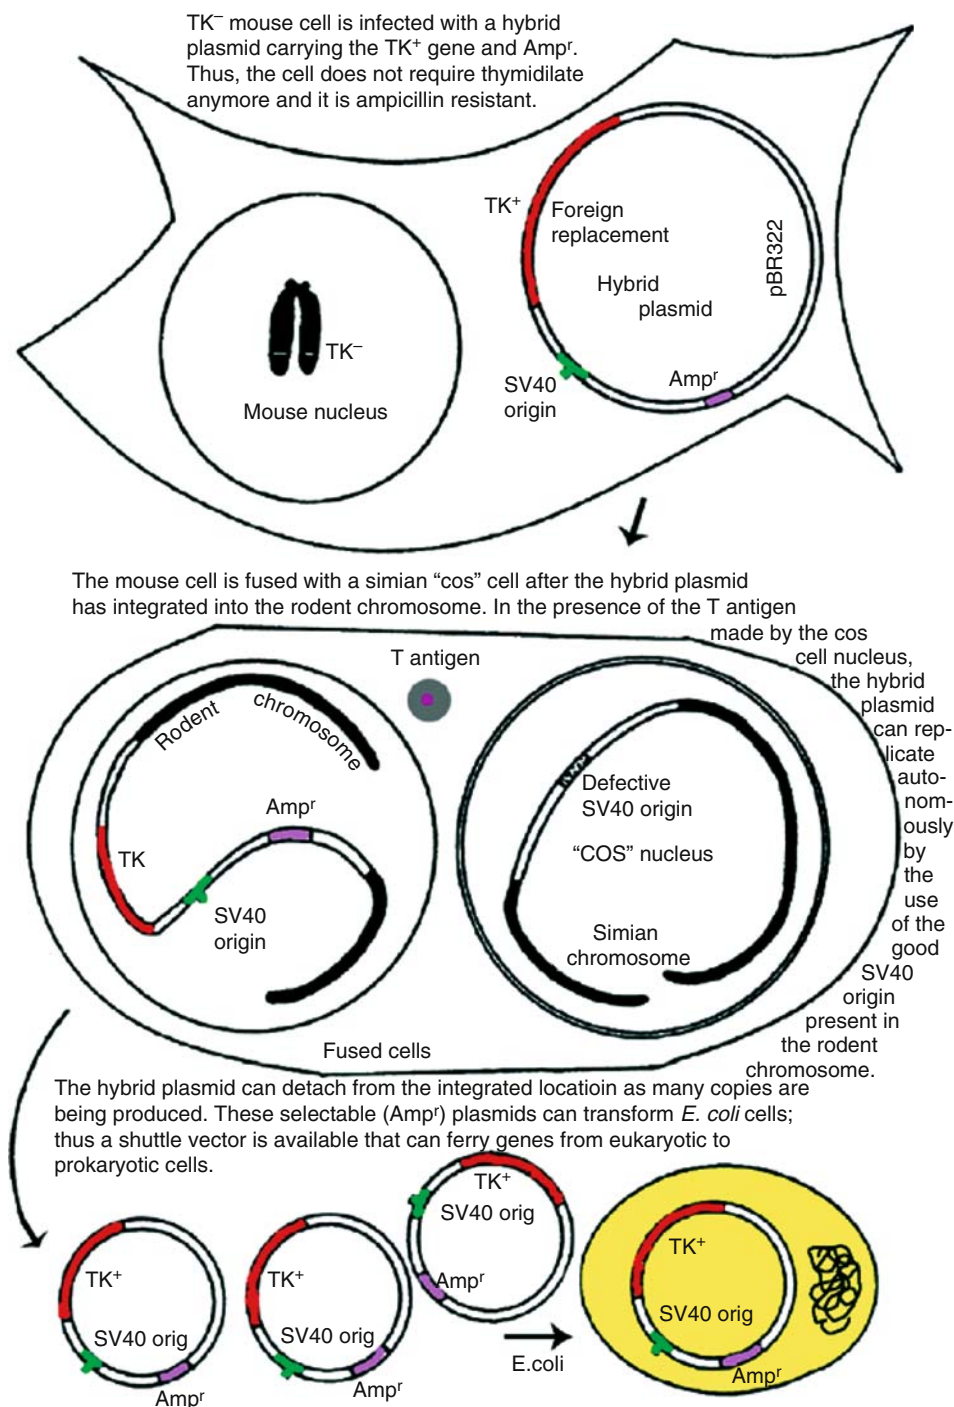

Figure S144. SV40 shuttle vectors can ferry genes from mammals to prokaryotes

The procedure: a thymidine kinase-deficient (*tk*⁻) rodent cell is transformed by pBR322 bacterial plasmid carrying the *ori* of SV40 and the TK⁺ (functional thymidine kinase), and an ampicillin resistance gene (*amp*^R) for bacterial selectability. Within the rodent cell the bacterial plasmid is integrated into a chromosome of the rodent cell and

this cell is then fused with a COS cell. The integrated pBR322 plasmid is replicated into many copies thanks to the presence of the COS nucleus. The hybrid plasmid carrying a bacterial replicon, an SV40 *ori*, the TK⁺ and *amp*^R can infect *E. coli* cells and can be selectively propagated there. Thus, the shuttle function is achieved. Another SV40 and pBR322

based vector is the pSV plasmid. This contains, in a Pvu II and HinD III restriction enzymes generated fragment, the promoter signals and the mRNA initiation site. When any open reading frame is attached to it, transcription can proceed. In addition, an intron of the early region provides splicing sites for other genes. The region also contains the transcription termination and polyadenylation signals. Some other pBR322 parts may be equipped with additional specific, selectable markers. ▶[Simian virus 40](#), ▶[vectors](#), ▶[viral vectors](#), ▶[shuttle vector](#); Jayan GC et al 2001 Gene Ther 8:1033; see Fig. [S144](#).

Switching, Phenotypic: May occur without any change in the genetic material and involves only altered regulation of transcription resulting in different phenotypes.

Swivelase (topoisomerase type I): After a single nick in a supercoiled DNA, it permits the cut strand to make a turn around the intact one to relieve tension. ► DNA replication, ► prokaryotes, ► topoisomerase; Zhu Q et al 2001 Proc Natl Acad Sci USA 98:9766.

SWR: ► chromatin remodeling

SWR Mouse: Prone to cancer and autoimmunity.

Swyer Syndrome (gonadal dysgenesis XY type, Xp22.1-p21.2): Apparently mutation or loss in the SRY gene is responsible for the anomaly. The afflicted individuals appear normal females until puberty but display only deficient (“streak”) gonads and fail to menstruate. ► gonadal dysgenesis, ► testicular feminization, ► SRY, ► sex determination, ► Denys-Drash syndrome

Sxl (sex lethal): (chromosomal location 1-19.2) Controls sexual dimorphism in *Drosophila*; it is required for female development. ► sex determination

SXR (steroid xenobiotic receptor in humans): Its mouse homolog is Pxr. This protein is an inducer of the cytochrome P450 detoxifying enzyme CYP3A4 (7p22.1). Mice transgenic for SXR displayed enhanced protection against environmental and drug carcinogens. This system also has important role in the oxidative activation of procarcinogens such as aflatoxin B and many different drugs. Apparently, the herb St. John’s wort, which may lower the effectiveness of the antiseizure phenobarbital, breast cancer drug tamoxifen, the contraceptive ethinyl estradiol, etc., activates SXR/Pxr. ► cytochromes; Synold TW et al 2001 Nature Med 7:536.

Sybase: A computer program that links various databases for macromolecules such as GeneBank, EMBL. ► data management system, ► databases; <https://login.sybase.com/login/userLogin.do>.

Sycamore (*Platanus* spp): Large attractive monoecious trees, 2n = 42.

SYK (M_r 72 K): A signal protein for the interleukin-2, granulocyte colony-stimulating factor and for other agonists. It is a protein tyrosine kinase of the SRC

family and indispensable for B lymphocyte development. Syk is downregulated by the Cbl protein. Syk seems to modulate epithelial cell growth and may suppress human breast carcinomas. ► B cell, ► ZAP-70, ► agonist, ► B lymphocyte receptor, ► Cbl, ► BTK; Sada K et al 2001 J Biochem 130:177.

Syllogism: A form of deductive reasoning using a *major premise*, e.g., mice show graft rejection, the rejection of transplants is based on the presence of the MHC system (*minor premise*), and therefore mice must have a major histocompatibility system (*conclusion*). ► logic

Symbionts: Mutually interdependent cohabiting organisms, such as the *Rhizobium* bacteria within the root nodules of leguminous plants, or algae within green hydra animals. The boundary between pathogenesis and mutualistically advantageous situation is not always clear. Many symbionts are essential for nutrition, digestion, development, and defense against other pathogens whereas others are definitely harmful for the health or reproduction of the host.

The leaf-cutting ants rear and feed only a single species of fungus through millions of years and develop mutualistic relations with it (Poulsen M, Boomsma JJ 2005 Science 307:741). Some wasps (*Philanthus triangulum*) cultivate *Streptomyces* bacteria in their antennal glands and apply them to the blood and this protects the cocoon from fungal infestation (Kaltenpoth M et al 2005 Curr Biol 15:475). Symbiosis may lead to loss or inactivation of genes that are no longer necessary in a cohabiting situation. The marine worm *Olavius algarvensis* lack mouth, gut and nephridia (excretory organs) and the nutritional functions are supplied by the cohabiting sulphur-oxidizing and sulphate reducing bacteria (Woyke T et al 2006 Nature [Lond] 443:950). On the other hand, new functions may be acquired or pre-existing gene functions may be enhanced that are mutually beneficial. Symbiosis may be interpreted either as mere cohabitation or a mutually meaningful association (advantageous or parasitic). Bacterial nitrogen fixation and mycorrhizal symbiosis is controlled by a ligand-gated cation (Ca²⁺, calmodulin) channel (Lévy J et al 2004 Science 303:1361). Calcium spiking is one of the initial steps in the symbiotic process. The proteins for establishing the symbiotic relationship for both fungi and bacteria reside in the plastids of the plant roots (Imaizumi-Anraku H et al 2005 Nature [Lond] 433:527). The plant pathogenic fungus *Rhizopus* harbors intracellular *Burkholderia* bacteria, which are responsible for the production of a polyketide, rhizoxin toxin. The toxin poisons β-tubulin and has strong antimitotic effect and, thus, can have medical use as an anticancer

agent (Partida-Martinez LP, Hertweck C 2005 Nature [Lond] 437:884). ►mycorrhiza, ►nitrogen fixation, ►mutualism, ►*Piriformospora indica*; Bermudes D, Margulis L 1987 Symbiosis 4:185; Currie CR 2001 Annu Rev Microbiol 55:357; mutualistic symbiosis among insects, bacteria and viruses: Moran NA et al 2005 Proc Natl Acad Sci USA 102:16919.

Symbionts, Hereditary: Occur in a wide range of eukaryotic organisms and their maternal transmission simulates extranuclear inheritance. They may be more wide spread than recognized. The temperate viruses of prokaryotes and the retroviruses may also be classified along these groups. In some strains of the unicellular protozoa, *Paramecium aurelia*, carrying the *K* gene, bacteria (e.g., *Caedobacter taeniospiralis*) live in the cytoplasm and is transmitted to the progeny. The first such infectious particles were named kappa (κ) particles before their bacterial nature was recognized, and were supposed to be normal extranuclear, hereditary elements. Many of these kappa particles contain R (refractive) bodies that are bacteriophages. The κ particles with R bodies appear "bright" under the phase-contrast microscope. The non-bright cells may give rise to bright, indicating that the phages are in the free and infectious stage and the brights are in the integrated, proviral stage. The virus directs the synthesis of toxic protein ribbons that are responsible for killing kappa-free paramecia ($\kappa\kappa$). The strains carrying the dominant *K* gene are immune to the toxin. Other strains have been discovered carrying different infectious particles lambda, sigma, mu that also make toxins. The mu particles do not liberate free toxin and kill only the cells with which they mate (mate killer). Other symbionts delta, nu and alpha are not killer symbionts.

In *Drosophila* strains Rhabdovirus σ may be in the cytoplasm and responsible for CO₂-sensitivity. Normal flies can be anesthetized with the gas for shorter periods without any harm. Those, which carry the virus may be paralyzed and killed by the same gas treatment. This virus is similar to the vesicular stomatitis virus of horses that cause fever, eruptions and inflammation in the mouth of horses, and to the fish rhabdovirus. In the non-stabilized strains, only the females transmit the virus to part of the progeny (depending on whether a particular egg does or does not contain the virus). Some of the non-stabilized may become stabilized. Stabilized strains transmit it through nearly 100% of the eggs and even some of the males transmit σ with some of the sperm yet the offspring of the male will not become stabilized. The *ref* mutants in chromosomes 1, 2 and 3 are refractory to infection. In some strains, there are mutants of the virus that are either temperature-sensitive or constitutively unable to cause CO₂ sensitivity although

they are transmissible. Different ribosomal picorna-viruses can be harbored in *Drosophila* that may reduce the life and fertility of the infected females. Females with the sex ratio (SR) condition produce no viable sons and the transmission is only maternal. In their hemolymph (internal nutrient fluids) the females carry spiroplasmas, bacteria without cell wall. If the infection is limited to the XX sector of gynanders, they may survive but not if the infection is in the XO sector. Triploid intersexes or females, phenotypically sterile males because of the genes *tra* (*transformer*, chromosome 3-45), *ix* (*intersex* gene located at 2-60.5) or *dsx* (*double-sex*, intersexes, chromosome 3-48.1) are not killed. Their special viruses may destroy the spiroplasmas. In plants (petunia, sugar beet), cytoplasmically inherited male sterility can also be transmitted by grafting. Some of the variegated tulips (broken tulips) are infected by viruses and had special ornamental value. During the seventeenth and eighteenth century "tulip mania," some rich Europeans paid the mainly Turkish and Persian merchants for the bulbs of the most attractive varieties, in equal weights in gold. ►lysogeny, ►cytoplasmic male sterility, ►extranuclear inheritance, ►*Drosophila*, ►aphids, ►meiotic drive, ►segregation distorter, ►broken tulips, ►sex determination, ►*Wolbachia*, ►*Spirochetes*, ►*Paramecia*, ►endosymbiont theory, ►pathogenicity island; Preer JR 1975 Symp Soc Exp Biol 29:125; Ehrman L, Daniels S 1975 Aust J Biol Sci 28:133; review of bacterial symbionts: Dale C, Moran NA 2006 Cell 126:453.

Symbiosis: ►symbiont

Symbiosome: In legume root nodules 2 to 5 μ m structures enclosing (by peribacteroid membrane) 2 to 10 bacteroids. The fixed nitrogen is released through this membrane to the plant and reduced carbon is received by the bacteroids from the plant. ►nitrogen fixation

Symbols: ►gene symbols, ►*Drosophila*, ►pedigree analysis

Sympathetic Nervous System: Communicates with the central nervous system (CNS, brain) through the thoracic and lumbar parts of the spinal cord, controls the blood vessels in the various organs, and the involuntary movements (reflexes) of the body.

Sympatric: Populations have overlapping habitats; it may be a beginning of speciation. ► [speciation](#)

Sympatric Speciation: Species that live in the same, shared area, for some reason become sexually isolated. This is a relatively rare phenomenon because most commonly geographical isolation is the major factor in speciation. ► [allopatric](#), ► [parapatric](#); palm trees: Savolainen V et al 2006 Nature [Lond] 441:210; cichlid fish: Barluenga M et al 2006 Nature [Lond] 439:719.

Sympetaly: Fused petals in a flower, see e.g., ► [snapdragon](#)

Symphalangism, Proximal: Fusion of the carpal and tarsal bones (SYM1, 17q22) caused by a defect in the noggin protein. ► [noggin](#), ► [bone diseases](#)

Symphlast: Multinucleate giant cell.

Symplastic Domain: A regulatory (supracellular) unit of several cells within the body.

Symplekin: A CPEB and CPSF binding protein scaffold, essential for cytoplasmic polyadenylation of mRNA in connection with xGLD-2 poly(A) polymerase. ► [polyadenylation signal](#); Barnard DC et al 2004 Cell 119:641.

Symplesiomorphic: Two or more species sharing a primitive evolutionary trait. ► [plesiomorphic](#), ► [apomorphic](#), ► [synapomorphic](#)

Symport: Co-transportation of different molecules through membranes in the same direction.

SYN: A prefix indicating union of tissues named after.

SYN: ► [ANTI](#)

Synaesthesia: Involuntary physical experience of a cross-modal linkage, e.g., hearing a tone (an inductive stimulus) and seeing a color or perception of smell or taste (Beeli G et al 2005 Nature [Lond] 434:38).

Synapomorphic: Species sharing an apomorphic trait. ► [apomorphic](#), ► [plesiomorphic](#), ► [symplesiomorphic](#)

Synapomorphy: Shared derived characters that can be used to advance phylogenetic hypotheses. ► [simple-siomorphy](#); Venkatesh B et al 2001 Proc Natl Acad Sci USA 98:11382.

Synaps (synapse): The site of connection between neural termini at which either a chemical or an electric signal is transmitted from one neuron to another (or to another type of cell) (see Fig. S146). Neurotransmitter release occurs at the presynaptic active zones and at postsynaptic densities. There is now evidence that extrasynaptic (ectopic) transmission also occurs (Coggan JS et al 2005 Science 309:446).

Figure S146. Synaps

The neurotransmitter may diffuse across the synaps or the electric signal may be relayed from one cytoplasm to the other through a gap junction. The neurons must interpret the postsynaptic potentials (PSP) and integrate the excitatory (EPSP) and inhibitory (IPSP) paired pulse potentials. The leukocyte common antigen related (LAR) protein, liprin (encoded by gene *syd-2* in *Caenorhabditis*), regulates the differentiation of the presynaptic vessels. This protein has tyrosine phosphatase activity. Mitochondria normally accumulate close to the site of synaps and their movement is controlled by Miro mitochondrial GTPase (Verstreken P et al 2005 Neuron 47:365; Guo X et al 2005 Neuron 47:379). ► [neurotransmitters](#), ► [tyrosine phosphatase](#), ► [gap junction](#), ► [memory](#), ► [ionotropic receptor](#), ► [metabotropic receptor](#), ► [neuregulin](#), ► [heregulin](#), ► [synaptic scaling](#), ► [Dscam](#), ► [NMDA](#); Ziv NE 2001 Neuroscientist 7(5):365; 2002 Science 298:770–791; Yamada S, Nelson WJ 2007 Annu Rev Biochem 76:267; <http://syndb.cbi.pku.edu.cn>.

Synapse, Immunological: The adhesion (gap) between the T lymphocyte receptor and the antigen presenting cell carrying the MHC—antigen complex or the killer cell inhibitory molecules and the special T cell receptor. Cytotoxic killer cells destroy virus-infected and tumorigenic cells by delivering secretory lysosome granules to the synaptic targets. The delivery is mediated by transient contact of the centrosome and plasma membrane and it is driven by the reorganization of the actin cytoskeleton (Stinchcombe JC et al 2006 Nature [Lond] 443:462). ► [T cell](#), ► [MHC](#), ► [killer cell](#); Khan AA et al 2001 Science 292:1681; Bromley SF et al 2001 Annu Rev Immunol 19:375.

Synapse, Informational: A specialized cell-cell junction mediating chemical or electric communication and displays a supramolecular structure to mediate information transfer between cells. (See Dustin ML et al 2001 Annu Rev Cell Dev Biol 17:133).

Synapsins: Bind to actin filaments, microtubules, annexing, SH3 domains, calmodulins and important regulators of synaptic vesicles. ▶[actin](#), ▶[annexin](#), ▶[SH3](#), ▶[calmodulin](#), ▶[synaptic vesicles](#), ▶[synaps](#)

Synapsis: Intimate chromosome pairing during meiosis between homologous chromosomes that may lead to crossing over and recombination (see Fig. S147). In some instances, non-homologous chromosomes or chromosomal regions may also associate. Protein-mediated synapsis involves recombination facilitated by integrases. Unpaired DNA causes meiotic silencing in *Neurospora* (Shiu PK et al 2001 Cell 107:905). Similarly in mouse in unsynapsed chromosomes the tumor suppressor BRCA1 and the kinase ATR co-localize to meiotic nodules (recombination nodules) and apparently because of the lack of phosphorylation of H2AX histone associated with the X and Y chromosomes asynapsis, sterility and apoptosis results (Turner JMA et al 2005 Nature Genet 37: 41). ▶[pairing](#), ▶[illegitimate pairing](#), ▶[meiosis](#), ▶[crossing over](#), ▶[synaptonemal complex](#), ▶[res](#), ▶[topological filter](#), ▶[tracking](#), ▶[integrase](#), ▶[asynapsis](#), ▶[histone variants](#), ▶[breast cancer](#), ▶[recombination nodule](#), ▶[ATR](#); McClintock B 1930 Proc Natl Acad Sci USA 16:791; Romanienko PJ, Camerini-Otero RD 2000 Mol Cell 6:975; Baudat F et al 2000 Mol Cell 6:989; minireview: McKim KS 2005 Cell 123:989.

Figure S147. Synapsed homologous chromosomes (2 pairs)

S

Synapsis, Bimolecular: Occurs between complementary ends of different/separate transposable elements. ▶[transposable elements](#)

Synaptic Adjustment: The degree of synapsis may change during meiosis in certain chromosomal regions. ▶[synapsis](#)

Synaptic Cleft: Electric neuronal signals are transmitted from the presynaptic cell to the postsynaptic cell by the gap called the synaptic cleft. ▶[neuron](#), ▶[synaptosome](#)

Synaptic Scaling: A bidirectional phenomenon in which excitatory synapses scale up in response to activity

reduction but scale down in response to increases in activity of neurons. Synaptic scaling is mediated by the pro-inflammatory cytokine, tumor-necrosis factor- α (TNF- α) of the glia. ▶[neuron](#), ▶[glia](#), ▶[synaps](#), ▶[TNF](#); Stellwagen D, Malenka RC 2006 Nature [Lond] 440:1054.

Synaptic Vesicles: Originate from endosomes, and store and release the neurotransmitters and other molecules required for signal transmission between nerve and target cells. Ca^{2+} regulates their function. ▶[neurotransmitters](#), ▶[syntaxin](#), ▶[RAB](#), ▶[synaptotagmins](#), ▶[synaptophysin](#), ▶[NSF](#), ▶[neuromodulin](#), ▶[neurogenesis](#); Cousin MA, Robinson PJ 2001 Trends Neurosci 24:659.

Synaptnemal Complex: ▶[synaptonemal complex](#)

Synaptobrevins (VAMP): ▶[syntaxin](#), ▶[SNARE](#)

Synaptogamins: Integral membrane proteins, binding calcium and interacting with other membrane proteins in the synaptic vessels of the nerves. Synaptogamins may interact with the different types of PtdIns and Ca^{2+} . ▶[neurexin](#), ▶[botulin](#), ▶[synaptic vesicles](#), ▶[SNARE](#), ▶[phosphoinositides](#), ▶[clathrin](#), ▶[Ipk1](#); Li C et al 1995 Nature [Lond] 375:594; Südhof TC 2002 J Biol Chem 277:7629.

Synaptogyrin: Membrane proteins; may be phosphorylated on tyrosine. (See Zhao H, Nonet ML 2001 Mol Biol Cell 12:2275).

Synaptojanin: A neuron-specific phosphatase (M_r 145,000) working on phosphatidylinositol and inositols and its putative role is in the recycling of synaptic vesicles. Its defect is responsible for Lowe's oculocerebrorenal syndrome. It binds to the SH3 domain of Grb2. ▶[synaptotagmin](#), ▶[syntaxin](#), ▶[Lowe's oculocerebrorenal syndrome](#), ▶[Grb2](#), ▶[dynamin](#); Khvotchev M, Südhof TC 1998 J Biol Chem 273:2306; Ha SA et al 2001 Mol Biol Cell 12:3175.

Synapton: same as synaptonemal complex.

Synaptonemal Complex: Proteinaceous element between paired chromosomes in meiosis. In yeast—analyzed by green fluorescent protein labeling—the complex is initiated at zygotene and by pachytene it forms a ribbon-like structure. At diplotene the complex falls apart yet the association of the homologs continues because of the mature chiasmata (White E et al 2004 Genetics 167:51). They consist of two lateral and a central element (see Fig. S148). Denser spots within it are called recombination nodules and were supposed to have a role in genetic recombination. It is supposed that the complex holds in place the recombination intermediates rather than actively promoting the process. Actually, in some

fungi (*Saccharomyces*, *Aspergillus*) no synaptonemal complex is observed and concomitantly chromosome interference is absent. These observations led to the assumption that the complex is responsible for interference rather than recombination.

Figure S148. The tripartite structure may be visible from interphase through diplotene. (Electronmicrograph by the courtesy of Dr. H.A. McQuade. Interpretative drawing after Comings DE, Okada TA 1970 Nature [Lond] 227:451)

Actually, recombination may precede the formation of the synaptonemal complex, thus, the role of the complex in interference may be questionable. In *Drosophila*, synaptonemal complex may be formed in the absence of meiotic recombination (crossing over or gene conversion), however, in the male flies both the synaptonemal complex and meiotic recombination are absent yet mitotic recombination may be observed.

►synapsis, ►meiosis, ►interference, ►recombination mechanism eukaryotes, ►association site, ►recombination nodule, ►single-end invasion, ►crossing over, ►mitotic crossing over, ►male recombination; Westergaard M, von Wettstein D 1972 Annu Rev Genet 6:71; Schmekel K et al 1993 Chromosoma 102:669; Solari AJ 1998 Methods Cell Biol 53:235; Heng HH et al 2001 Genome 44:293; Page SL, Hawley RS 2004 Annu Rev Dev Biol 20:525; Lynn A et al 2002 Science 296:2222.

Synaptophysin: Membrane-spanning proteins in the synaptic vessel involved in neurotransmitter release. ►synaptic vessel, ►neurotransmitter, ►ceroid lipofuscinosis

Synaptosome: The protein complex mediating interactions among neurotransmitters and receptors across the synaptic cleft. ►neurotransmitter; Husi H, Grant SG 2001 Trends Neurosci 24:259.

Synaptotagmins: Proteins in the synaptic vesicles and have a role in Ca^{2+} -involved release of neurotransmitters, and in general in exo- and endocytosis. Exocytosis of synaptic vesicles is controlled by complexin and synaptotagmin (Tang J et al 2006 Cell 126:1175). ►synaptotagmin, ►syntaxin, ►complexin, ►synapse, ►SNARE; Fernandez-Chacon R et al 2001 Nature [Lond] 410:41; Hui E et al 2005 Proc Natl Acad Sci USA 102:5210.

Synchronous Divisions: The cells are at the same stage of the cell cycle.

Synchrotron: Radiation emitted by high-energy, high-speed electrons accelerated in magnetic fields. The range varies from infrared to hard X-rays. Their high energy permits to study their effects also in monochromatic forms. ►ionizing radiation; <http://www.srs.ac.uk/srs/>.

Synclinal: ►anticlinal

Syncytial Blastoderm: An early stage of embryogenesis when the single layer of nucleated cytoplasmic aggregates do not yet have a cell membrane. ►blastoderm

Syncytium: A collection of nuclei surrounded by cytoplasm without the formation of separate membranes around each, such as in early embryogenesis or among the progeny of a single spermatogonium or abnormal multinucleate cells or the plasmodia of slime molds. ►imaginal discs, ►blastoderm, ►Dictyostelium

Syndactyly: Webbing or fusion between fingers and toes (see Fig. S149). In polysyndactyly, mutation in the polyalanine extension of the amino terminal of human homeotic gene (HOX13) is the responsible factor. Syndactyly 1 was located to 2q34-q36. ►Poland syndrome, ►limb defects, ►Rubinstein-Taybi syndrome, ►Greig's cephalopolysyndactyly, ►GLI3 oncogene, ►homeotic genes, ►polysyndactyly, ►Pallister-Hall syndrome, ►Guttacher syndrome; Bosse K et al 2000 Am J Hum Genet 67:492.

Figure S149. Syndactyly

Syndecans: Heparan sulfate proteoglycans, membrane-spanning cell adhesion molecules and co-factor receptors bearing heparan sulphate proteoglycans distal from the plasma membrane. Syndecan promotes over-eating and obesity in mice. Syndecan-1 opposes the effect of the melanocyte-stimulating

hormone. Syndecan-1, -2, -3, -4 are encoded in human chromosome 2p23-p24, 8q23, 1p32-p36 and 20q12-q13, respectively. ►CAM, ►selectin, ►heparan sulphate, ►glypican, ►obesity, ►melanocyte-stimulating hormone; Reizes O et al 2001 Cell 106:105; Couchman JR 2003 Nature Rev Mol Cell Biol 4:926.

Syndrome: A collection of symptoms, traits caused by a particular genetic constitution. In humans, there are about 2000 syndromes determined mainly by single genes. The individual symptoms of different syndromes, however, may overlap among a large number of genetic and non-genetic disorders. Therefore, the precise identification is often an extremely difficult task. More accurate identification will probably be possible when the genome projects will provide structural and topological evidence for all the loci concerned. The *unknown genesis syndromes* usually occur sporadically yet they may have genetic bases. ►genome projects, ►association, ►non-syndromic, ►physical mapping, ►microarray, ►epistasis; Brunner HG et al 2004 Nature Rev Genet 5:545; human medical databases: <http://www.lmdatabases.com/>.

Synergids: Two haploid cells in the embryosac of plants flanking the egg. The pollen tube first penetrates one of the synergids, after the rupture of that synergid and rupture of the pollen tube the tube elongation is arrested, and the vegetative and the sperm nuclei fertilize the polar nuclei and the egg nucleus, respectively. The *FER* gene of *Arabidopsis thaliana* encodes a synergid-expressed, plasma membrane-localized, receptor-like kinase. The FER protein accumulates asymmetrically in the synergid membrane at the filiform apparatus. Interspecific crosses using pollen from *Arabidopsis lyrata* and *Cardamine flexuosa* on *A. thaliana* stigmas resulted in a *fer*-like phenotype that correlates with sequence divergence in the extracellular domain of FER. Our findings show that the female control of pollen tube reception is based on a *FER*-dependent signaling pathway, which may play a role in reproductive isolation barriers (Escobar-Restrepo J-M et al 2007 Science 317:656). ►gametogenesis, ►gametophyte, ►pollen tube; Higashiyama T et al 2001 Science 293:1480.

Synergistic Action: The participating elements enhance the reaction above the sum of the separate strength of their separate actions. ►interaction variance, ►epistasis

Synexpression Groups: Genes that are expressed together either spatially, temporally or developmentally. Their identification is facilitated by microarray hybridization. These groups do not need to be genetically linked and therefore are different from gene clusters or operons of prokaryotes that are linked. ►macroarray analysis, ►microarray hybridization,

►operon, ►clustering of genes; Nirehrs C, Pollet N 1999 Nature [Lond] 402:483.

Syngamy: The union of two gametes in fertilization leading potentially to the fusion of the two nuclei in the cell. ►plasmogamy, ►karyogamy, ►synkaryon, ►semigamy

Syngen: A reproductively isolated group of ciliates.

Syngeneic: Antigenically similar type cells (in a chimera). ►antigen, ►immunoglobulins

Synkaryon: A cell (zygote, fused conidia or spores) with a nucleus originated by the union of two nuclei. ►karyogamy, ►heterokaryon, ►dikaryon

Synonymous Codons: These have different bases in the triplet yet they specify the same amino acids. The 61 sense codons stand for 20 common amino acids. Some amino acids have up to 6 codons. Thus, mutation may not have any genetic consequence, except when exon splice site is involved. A synonymous single nucleotide polymorphism (SNP) in the *Multidrug Resistance 1 (MDR1)* gene, leads to altered function of the *MDR1* gene product P-glycoprotein (P-gp) and results in altered drug and inhibitor interactions. Although the mRNA and protein levels are similar, conformation was altered. Supposedly, the presence of a rare codon affects the timing of cotranslational folding and insertion of P-gp into the membrane, thereby altering the structure of substrate and inhibitor interaction sites (Kimchy-Sarfaty C et al 2007 Science 315:525). Some bases may affect the intensity of translation. In functional areas of the genome, synonymous substitutions are more common than non-synonymous ones. Purifying selection usually eliminates the deleterious non-synonymous mutations. Slightly deleterious non-synonymous substitutions can be maintained in bacterial populations with high effective population size (Hughes AL 2005 Genetics 169:533). ►genetic code, ►splicing, ►exon, ►intron, ►non-synonymous codon, ►radical amino acid substitution, ►effective population size, ►Grantham's rule

Synostosis: Bone fusion. ►noggin

Synovial Sarcoma: ►SYT

Synpolydactyly: ►polydactyly, ►polysyndactyly, ►syndactyly

Syntax: Sentence structure; organization of groups of words, phrases and clauses in the correct manner. The term is also used by computerized information retrieval.

Syntaxin: A synaptic membrane protein forming part of the nerve synaptic core complex along with the synaptosome associated protein and synaptobrevin (VAMP), a vesicle associated membrane protein. Omega-3 and omega-6 fatty acids act on syntaxin and stimulate membrane expansion (Darios F, Davletov B

2006 Nature [Lond] 440:813). Syntaxins are involved in vesicular transport between the endoplasmic reticulum and the Golgi apparatus as target membrane receptors. Syntaxin-5 is an integral part of the endoplasmic reticulum-derived transport vesicles. A synaptobrevin-like gene (SYBL1) was located to the pseudoautosomal region of the human X chromosome. It recombines with Y-chromosomal homolog, displays lyonization in the X chromosome, and is inactivated in the Y chromosome. A score of syntaxins have been identified in humans encoded at chromosomes 7q11.2, 17p12, 16p11.2, etc. ▶[synaptotagmin](#), ▶[SNARE](#), ▶[synaps](#), ▶[endoplasmic reticulum](#), ▶[Golgi apparatus](#), ▶[pseudoautosomal region](#), ▶[lyonization](#), ▶[Munc](#), ▶[cystic fibrosis](#), ▶[stoma](#), ▶[omega-3 fatty acids](#); Bennett MK et al 1992 Science 257:255; Mullock BM et al 2000 Mol Biol Cell 11:3137.

Syntelic Distribution: The kinetochores of the two sister chromatids are attached to spindle fibers that pull them to the same pole during mitotic anaphase.

Syntenic Genes: Within the same chromosome; they may, however, freely recombine if they are 50 or more map units apart. Gene blocks may display synteny among related taxonomic entities even when their chromosome number varies. Syntenic gene sets may provide information on phylogeny of the species. ▶[linkage](#), ▶[crossing over](#)

Syntenin: 32 kDa adaptor protein with two PDZ domains involved in cytoskeleton-membrane organization. ▶[PDZ](#), ▶[IL-5](#); Zimmermann P et al 2001 Mol Biol Cell 12:339; Cierpicki T et al 2005 Structure 13:319.

Synthases: Mediate condensation reactions of molecules without ATP. ▶[synthetases](#)

Synthetases: Mediate condensation reactions that require nucleoside triphosphates as energy source. ▶[synthases](#)

Synthetic Biology: A new area of science aiming either to introduce new (synthetic) molecules into existing organisms, or interchange existing molecules between organisms or chemically synthesizes new systems from known compounds, e.g., create synthetic viruses on the basis of the genetic code. This field includes from de novo organic synthesis, to genetic engineering, stem cell research, etc. Networks have been designed from natural transcription factors and binding sites. Its aims include creation of toggle switches, cellular oscillators, new forms of cell-to-cell communications and cell pattern formation. A beautiful paper reports the duplication and parallel modifications of the 16S prokaryotic ribosomal RNA (the anti-Shine-Dalgarno sequence, CCUCC) and the Shine-Dalgarno sequence (GGAGG) of the mRNA. The new ribosome may or may not function anymore

as the original one; the modified ribosome however can translate the modified mRNA. Through mutations in both the ribosomes and in the mRNA, various combinations of enormous variety of potential functions can be established and tried (Rackham O, Chin JW 2005 Nature Chem Biol 1:159).

Although this type of research can generate altered or new organisms that may pose unknown hazards, the potential advantages for agriculture and medicine outweigh the risks. ▶[genetic engineering](#), ▶[stem cells](#), ▶[synthetic genes](#), ▶[gene circuits](#), ▶[synthetic virus](#), ▶[influenza virus](#), ▶[protein engineering](#), ▶[oscillators](#); Benner SA, Sismour AM 2005 Nature Rev Genet 6:533; <http://syntheticbiology.org>.

Synthetic DNA Probes: If the amino acid sequence in the protein is known but the gene was not yet isolated, a family of synthetic probes may be generated to tag the desired gene. This probe is generally no longer than 20 base because of the difficulties involved in their synthesis. The genetic code dictionary reveals which triplets spell the amino acids. An amino acid sequence that uses few synonymous codons is selected. A computer match generally chooses the possible combinations. E.g., a probe for the His-Thr-Met peptide sequence would require the following 8 polynucleotide sequences to consider all possible sequences for a probe (see Fig. S150). The inclusion of **Methionine** (having a single codon) is simplifying the task. **Histidine** is relatively advantageous because it has only two synonymous codons. **Threonine** with four codons make the work more difficult; leucine, serine and arginine containing parts of the proteins should be avoided (because they have six codons) but tryptophan, also with a single codon would be highly desired. Insertion of ambiguous deoxyinosine nucleotides at some positions may facilitate the design of probes. ▶[probe](#), ▶[functional cloning](#), ▶[gene isolation](#); Ohtsuka E et al 1985 J Biol Chem 260:2605; Lichtenstein AV et al 2001 Nucleic Acids Res 29(17):E90.

Figure S150. Synthetic probe

Synthetic Enhancement: Basically an epistatic process by increasing or reducing interaction between gene products by using crossing, knockouts, transformation, etc.

Synthetic Genetic Networks: Constructs to simplify the understanding of regulated gene complexes. It is based on tools of nonlinear dynamics, statistical physics and molecular biology. ▶[genetic networks](#); McMillen D et al 2002 Proc Natl Acad Sci USA 99:679.

Synthetic Genomes: ▶[synthetic virus](#), ▶*Mycoplasma genitalium*, ▶[potentials of functional](#); synthetic microbial genomes: Holt RA et al 2007 BioAssays 29:580.

Synthetic Lethal (synthetic enhancement): Gene is inviable only in certain genetic constitutions. Thus, two single mutations have no or insignificant phenotypic consequence separately but the double mutant may be lethal. In yeast, only ~1000 of the genes are essential and 5000 are viable even when deleted. The synthetic lethals cells include more than one defective gene. Partners in synthetic lethal systems can be essential as well as non-essential genes. In gene networks, at least one of the genes must be essential although most of the non-essential genes can compensate for each other. Synthetic lethals may be involved in inbreeding depression and may be the cause of some hybrid inviabilities and sterility. A synthetic lethal test may be used in anticancer drug design by combining two different mutations that in combination, seriously impair cells to gain information on how to kill cancer cells. ▶[inbreeding](#), ▶[synthetic genetic array](#), ▶[synthetic genetic networks](#), ▶*Saccharomyces cerevisiae*; Jacobson MD et al 2001 Genetics 159:17; Davierwala AP 2005 Nature Genet 37:1147.

Synthetic Organisms: ▶[synthetic biology](#)

Synthetic Polynucleotides: Nucleic acid oligomers or polymers generated in the laboratory by enzymatic or other synthetic methods. Nucleic acid synthesizer machines produce some of them. (See Benner SA et al 1998 Pure Appl Chem 70:263).

Synthetic Seed: Somatic embryos encapsulated into a protective capsule (e.g., calcium alginate) and used for propagation in cases when regular seed is not available or homozygotes are difficult to obtain. ▶[artificial seed](#)

Synthetic Species: Amphidiploids of presumed progenitors of existing species obtained by crossing and diploidization. Some synthetic species have never existed in nature before as the *Raphanobrassica*, $2n = 36$, an amphidiploid of radish (*Raphanus sativus*, $n = 9$) and cabbage (*Brassica oleracea*, $n = 9$) (see Fig. S153). *Triticale*s are similarly new amphidiploids either $2n = 48$ or $2n = 56$, obtained by crossing tetraploid ($2n = 28$) or hexaploid ($2n = 42$) wheat (*Triticum*) with diploid rye (*Secale cereale*, $2n = 14$). Some synthetic species are only

reconstructions of the evolutionary form, e.g., *Nicotiana tabacum*, *Hylandra suecica*, *Primula kewensis*, etc. The entire *Mycoplasma* genome of one species has been transferred intact to another and entirely replaced that of the recipient, creating a new species. ▶[alien substitution](#), ▶[amphiploid](#), ▶*Mycoplasma*, ▶*Triticale*; *Raphanobrassica*: Karpetchenko GD 1928 Z Indukt Abstammungs Vererbungs 48:1.

Cabbage
Brassica oleracea, $2n = 18$

Raphanobrassica, $2n = 36$

Radish
Raphanus sativus, $2n = 18$

Figure S153. Synthetic *Raphanobrassica*

Synthetic Variety: Composed of several selected lines, which may reproduce by out-crossing within the group. ▶[polycross](#)

Synthetic Vector: ▶[liposome](#)

Synthetic Virus: The functional RNA poliovirus and the single-stranded DNA virus ϕ X174 have been assembled from synthetic oligonucleotides and the technology is already available to generate cellular genomes within the laboratory. ▶[polio virus](#), ▶ ϕ X174, ▶[influenza virus](#); Smith HO et al 2003 Proc Natl Acad Sci USA 100:15440.

Synthon: A synthetically produced molecule, in the laboratory.

Syntrophic: Can be maintained (only) by cross-feeding. Based on cross-feeding metabolic pathways of microorganisms could be identified on culture media. In a metabolic pathway $A \rightarrow B \rightarrow C \rightarrow D$ mutation blocked before D may cross-feed mutants blocked before C and B. Mutation blocked before C may facilitate the growth of mutants inactive in step B, and so on. A syntrophic hypothesis is that the mitochondria of eukaryotes evolved by the fusion of an achaeon, a δ -proteobacterium and an α -proteobacterium. ▶[cross-feeding](#), ▶[channeling](#)

Synuclein (α -synuclein, 4q21): A 140-amino acid protein in the presynaptic neurons, a major constituent of the Lewy bodies. All synucleins display imperfect KTKEGV amino acid motifs and a variable C-terminus. Synucleins are phosphorylated at Ser and

Tyr tail residues and this reduces aggregation. Hydrophobic residues 71-82 promote aggregation. α -synuclein promotes the fibrillization of tau in neurodegenerative diseases (Giasson BI et al 2003 Science 300:636). A truncated α -synuclein accumulates in the neuronal cells and promotes Parkinson disease (Li W et al 2005 Proc Natl Acad Sci USA 102:2162). It interacts with synphilin-1 for normal function. In the oxidized or nitrated forms synuclein aggregates and may cause the synucleinopathies such as Parkinson disease, Alzheimer disease, amyotrophic lateral sclerosis and Huntington disease. In the majority of cases of sporadic Parkinson disease (PD) several mutant genes have been identified. The principal genes that cause (PD) are alpha-synuclein, parkin, leucine-rich repeat kinase 2 and PTEN-induced putative kinase 1 (Wood-Kaczmar A et al 2006 Trends Mol Med 12:521). Beta synuclein gene, also expressed in the brain in Alzheimer disease, was assigned to 5q35, gamma synuclein/persyn (in breast cancer) to 10q23.2-q23.3. ▶[Lewy body](#), ▶[neurodegenerative diseases](#), ▶[Parkinson disease](#), ▶[alcoholism](#), ▶[PTEN](#); Touchman JW et al 2001 Genome Res 11:78; Shimura H et al 2001 Science 293:263; Cuervo AM et al 2004 Science 305:1292.

SYP: A tyrosine phosphatase.

Syphilis: ▶[Treponema pallidum](#)

Sypro Ruby: A sensitive protein stain used in 2-dimensional gel electrophoresis.

Syringa: ▶[lilac](#)

Syringe Filter: A syringe equipped with a commercially available sterilizing filter block (0.45 or 0.20 μ m pores) and removes microbial contaminations instantly without heating (see Fig. [S154](#)).

Figure S154. Syringe filter

Syringomyelia: A rare autosomal dominant or autosomal recessive cavitations (formation of cavities) in the spinal cord. It may be also due non-hereditary causes.

System Biology: Biological phenomena can be fully understood only by learning their complex interacting networks. (Kitano H 2002 Curr Genet 41:1).

Systematic Error: The same bias affects all measurements or observations.

Systematics: A method of classification such as taxonomy. Carl Linné (Linnaeus) Swedish botanist (1707–1778) initiated the classification and binomial nomenclature of organisms.

Systemic: Affects the entire cell or the entire body of an organism.

Systemic Acquired Resistance: ▶[SAR](#)

Systemic Amyloidosis, Inherited: An extracellular deposition of fibrous proteins in the connective tissues under autosomal dominant control. ▶[amyloidosis](#)

Systemic Genes: Cell autonomous versus genes, regulated by intercellular communication.

Systemin: An 18-amino acid signaling peptide for plant defense mechanisms. ▶[plant defense](#), ▶[host-pathogen relation](#)

Systemoid: Similar to a system, alternatively it is used to denote tumors that include different types of tissues. ▶[teratoma](#)

Systems Biology: Studies biological mechanisms by monitoring gene, genome, protein, proteome and informational pathways systematically using all possible, suitable means. The genes control metabolic functions and are associated with regulatory elements. The proteins may function in complexes and networks and through systems of interacting networks. The simplest controls of the genes are exercised through cis elements such as general and specific transcription factors. The genes are also subject to external signals (signal transduction). The different elements of these systems may change dynamically and thus physiological and developmental modifications arise such as in the healthy or pathologically affected conditions (Hood L et al 2004 Science 306:640). Systems biology separates the effects of noise, and permits the development of rational models and offers new approaches for controlling complex system of the cells, tissues and organisms using bioinformatics, biological and molecular methods. It permits prediction regarding emergent complex phenomena involving, and may enable preventive, predictive and personalized medicine. The components of the system may respond dynamically to different stimuli in time and space and follow different trajectories before steady state is reached (Barbano PE et al 2005 Proc Natl Acad Sci USA 102:6245). A new method has been developed for integration of multiple datasets by using a free software (POINTILLIST) package (Hwang D et al 2005 Proc Natl Acad Sci USA 102:17296). The method was successfully applied to 18 datasets of galactose utilization of yeast involving mRNS, protein

abundance, genome-wide protein interaction data, etc. (Hwang D et al 2005 Proc Natl Acad Sci USA 02:17302). Because of the rapid progress in experimental research and the increasing number of databases containing important relevant information, new bioinformatic tools are indispensable for integration of the knowledge. The databases must be found and the data must be converted into forms suitable for integration by electronic means. Modern database management system must be expanded and appropriate interfaces must be used. The Trace Ensemble Server only on Unix system (<http://trace.ensembl.org/>) already contains more than one billion information about 759 species. ►genetic networks, ►networks, ►drug development, ►ONDEX, ►databases; Recon H-InvDB Hood L, Galas D 2003 Nature [Lond] 421:444; Ideker T et al 2001 Annu Rev Genomics Hum Genet 2:343; Shogren-Knaak MA et al 2001 Annu Rev Cell Dev Biol 17:405; Philippi S Köhler 2006 Nature Rev Genet 7:482; software standardization: Swertz MA, Jansen RC 2007 Nature Rev Genet 8:235; <http://bind.ca/>; <http://www.cytoscape.org>; network tool: <http://biologicalnetworks.net/>; system biology tool: <http://babelomics.bioinfo.cipf.es/>.

Systems of Breeding: Sexual reproduction may be allogamous, autogamous, inbreeding, assortative mating, hermaphroditic, monoecious and dioecious but reproduction may also be asexual. ►breeding system

Systole: Contraction of the heart and the forcing of the blood into the arteries. ►hypertension

SYT (synovial sarcoma): Oncogene in human chromosome 18q11.2. Translocations t(X;18) (p11;q11) are common. Gains of 8q and 12q as well as losses of 13q and 3p are frequent.

SZI: ►micromanipulation of the oocyte

Szostak Model of Recombination (Szostak JW et al 1983 Cell 33:25): A double break and repair model. It is applicable to transformational insertion of DNA molecules as well, as it can account for gene conversion and/or conventional recombination by outside marker exchange. The version of the model shown in Figure S155 does not explain why in yeast 5:3 gene conversion does not occur. (*Saccharomyces cerevisiae* has 4 spores per ascus but *Schizosaccharomyces pombe* has 8 unordered ascospores.)

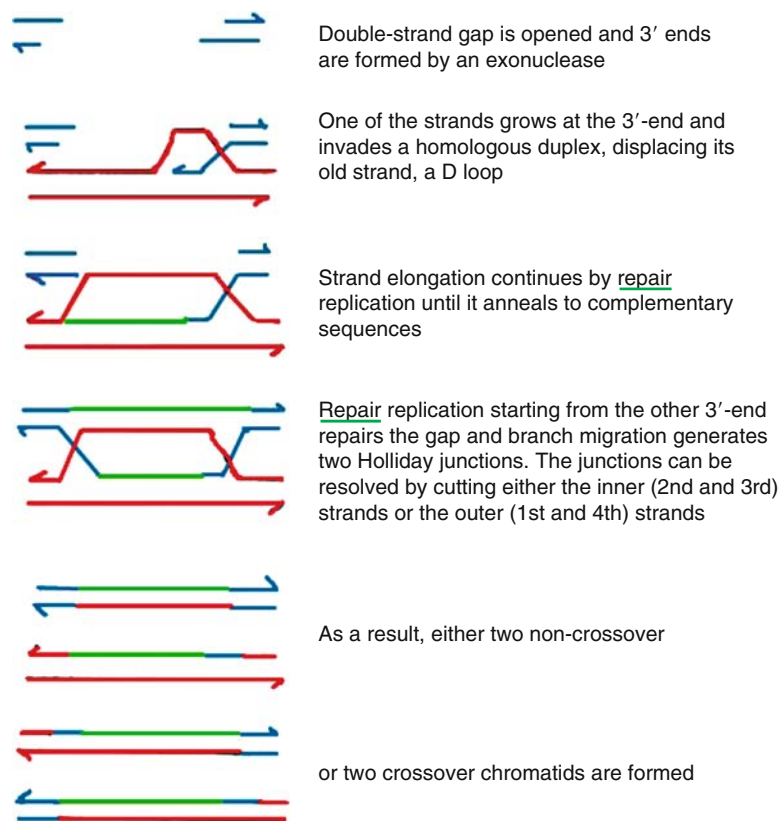

Figure S155. The Szostak et al model of recombination is based on double-strand breaks in contrast to the Holliday or the Meselson—Radding models that suggest single-strand breaks in the DNA

Other modified models of Szostak can account for these types of experimental data. Genetic recombination in eukaryotes generally occurs by double-strand break. Radiation and various chemicals can increase the frequency of double-strand breaks.

Double-strand breaks can also be increased in plant cells by transformation of a restriction endonuclease into the cell. ►[recombination molecular models](#); Szostak JW et al 1983 Cell 33:25; Smith GR 2000 Annu Rev Genet 34:243, see Fig. [S155](#).

Historical vignettes

Wilson EB 1896 The Cell in Development and Heredity. Macmillan, New York.

“Now, chromatin is known to be closely similar to, if not identical with, a substance known as nuclein—which analysis shows to be a tolerably definite compound composed of nucleic acid (a complex organic acid rich in phosphorous) and albumin [protein]. And thus we reach the remarkable conclusion that the inheritance may, perhaps, be effected by the physical transmission of a particular chemical compound from parent to offspring.”

Linus Pauling’s letter to S Leonard Wadler on August 15 1966. (Cited after the Oregon State University Manuscript Collection). Pauling received Nobel Prize in 1954 for the nature of the chemical bond and again in 1962 for peace.

“I have suggested that the time may come in the future when information about heterozygosity in such serious genes as the sickle cell anemia gene would be tattooed on the forehead of the carriers, so that young men and women would at once be warned not fall in love with each other.”

Kingman JFC 2000 in Genetics 156, p 1463
“Those who analyze stochastic models always lift their eyes from their equations to ask what they actually mean.”

θ: The symbol of recombination (and some other) fractions. ▶ [w](#)

T2: A virulent bacteriophage. ▶ [bacteriophages](#), ▶ [T4](#)

T4: A virulent (lytic) bacteriophage of *E. coli*. It has double-stranded DNA genetic material of 1.08×10^6 Da (about 166 kbp) with a total length of about 55 μm. Its cytosine exists in hydroxymethylated and glycosylated forms. The linear DNA is terminally redundant and cyclically permuted. The redundancy occupies more than 1% of the total DNA. It was an unexpected discovery that its thymidylate synthetase gene contains an intron. Introns are common in eukaryotes but exceptional in prokaryotes. The phage has over 80 genes involved in metabolism but only about a fourth of them are indispensable. The metabolic genes control replication, transcription, and lysis. Other metabolic genes have functions overlapping those of the host. After infection, the phage turns off or modifies bacterial genes, degrades host macromolecules, dictates the transcription of its own genes, and utilizes the host machinery for its own benefit. For the synthesis of its own DNA, it relies on the nucleotides coming from the degradation of the host DNA. The bacterial RNA polymerase transcribes the phage genes. The viral protein Alc interacts with the β subunit of the host and terminates transcription on templates with cytosine residues. The viral DNA contains hydroxymethyl cytosine, which can serve as a template. The cytidylic acid residues of the host are prevented from being incorporated into the phage DNA by phosphatases. A deaminase converts them to thymidylic acid or a methylase enzyme converts them to hydroxymethyl cytosine through a few steps. The hydroxymethylcytidylate is

then glucosylated by a glucosyl transferase enzyme. The molar proportion of thymidylate is higher in T4 than in *E. coli*, presumably because of the conversion of cytidylate into thymidylate. A series of more than 50 genes are involved in morphogenesis. At least 40% of the genome is required for the synthesis and assembly of the viral particle. 24 genes mediate head assembly, while the baseplate and tail require at least 31 genes. ▶ [development](#), ▶ [one-step growth](#), ▶ [bacteriophages](#), ▶ [sliding clamp](#); Calendar R (Ed.) 1988 The Bacteriophages, Plenum, New York; Knipe DM, Howley PM (Eds.) 2001 Fundamental Virology, Lippincott Williams & Wilkins, Philadelphia, Pennsylvania.

T Alleles: ▶ [Brachyury](#)

T Antigen: The T antigen of SV40 virus is a 708-amino acid multifunctional protein and an effector of DNA polymerase α function. It assists in separating the DNA strands for replication and generates the replication bubble as the polymerase moves on. It has a special role in SV-induced tumors after tumor-suppressor proteins are eliminated or weakened. The T antigen and sequentially similar proteins are also factors in nuclear localization. ▶ [Simian virus 40](#), ▶ [SV40](#), ▶ [nuclear localization sequences](#); Li D et al 2003 Nature [Lond] 423:512; Sullivan CS, Pipas JM 2002 Microbiol Mol Biol Rev 66:179.

t Antigen: The t antigen shares the same N-terminal sequences with the T antigen but the carboxyl end is different. The t antigen has homology to the G_t protein, an α subunit of the trimeric G-proteins involved in the activation of cGMP phosphodiesterase involved in photoreception and other processes. ▶ [Simian virus 40](#), ▶ [G-proteins](#)

T Band: ▶ [T-band](#)

T Box (Tbx): A conserved ~14-nucleotide DNA domain upstream of the transcription terminator of Gram-positive bacteria in about 250 genes encoding aminoacyl-tRNA synthetases, and amino acid biosynthetic and transport enzymes. Uncharged tRNAs appear to interact with the leader sequence of these genes by their amino acid-accepting termini at the middle of the T box (UGGN') to stabilize antitermination at the expense of the terminator. T box genes (although named differently) occur in all species. In humans sequencing, the genome identified at

least 18. These are generally transcription factors and are specific to diverse downstream genes. T box proteins interact with each other (through heterodimerization) and with many other proteins. They are involved in Wnt (winged), TGF- β (transforming growth factor), hedgehog, FGF (fibroblast growth factor), Notch, and receptor guanylate phosphate signaling. Several developmental disorders and human diseases are due to T box genes, which show both positive and negative effects on development. ▶*antitermination*, ▶*MAR*, ▶*Brachyury*, ▶*eomesodermin*, ▶*Holt-Oram syndrome*, ▶*DeGeorge syndrome*, ▶*Scheinzel syndrome*, ▶*T-bet*; Papaioannou VE, Silver LM 1998 *Bioessays* 20:9; Smith J 1999 *Trends Genet* 15:154; Putzer H et al 2002 *Nucleic Acids Res.* 30:3026; Showell C et al 2004 *Dev Dyn* 229:201; Naiche LA et al 2005 *Annu Rev Genet* 39:219.

T Cell Receptor (TCR): T cell surface glycoproteins recognize antibodies. The differentiation of the T cells begins with the differentiation of their receptors. At the beginning, the TCR is double negative, i.e., it is CD4⁻ CD8⁻. The disulphide-linked heterodimers have α and β or γ and δ chains, containing variable and constant regions and are homologous to the corresponding antibodies. First, the TCR β is rearranged, followed by the rearrangement of the α chain. At this stage, the β chain may signal allelic exclusion and this means the end of rearrangements. After this, the double positive (DP) stage follows, i.e., CD4⁺ CD8⁺ TCR appears. A selection process ensues, resulting in an array of self MHC-restricted and self-tolerant TCRs. The TCR α chain is a transmembrane protein and the cytoplasmic (carboxyl) end has two potential phosphorylation sites and a Src homology 3 (SH3) domain (see Fig. T2). The TCR β chain regulates the development of the T cells in the absence of the α chain. The $\alpha\beta$ TCR generally recognizes antigens bound to the major histocompatibility (MHC) molecules. The TCR complex also

includes the CD3 protein, required for signal transduction. It is made of the γ , δ , ϵ , and ζ chains. The ζ chain plays a role in thymocyte development but it is not indispensable for signal transduction. The chromosomal site of the human α (14q11), β (6q35), γ (7p15-p14), δ (14q11.2), and ζ (1p22.1-q21.1) chains are shown in parenthesis. Marsupials also have TCR μ that does not have a known homolog in eutherian mammals but has features analogous to a TCR isoform in sharks (Parra ZE et al 2007 *Proc Natl Acad Sci USA* 104:9774).

Activation is triggered when the T cell receptor binds the MHC associated ligand on the antigen presenting cell (Choudhuri K et al 2005 *Nature [Lond]* 436:578). Co-stimulating signals may help. The CD3 component of the TCR may be altered, and protein tyrosine kinases (PTK) are activated. The PTKs may turn on the calcium-calcineurin, the RAS-MAP, and the protein kinase signaling pathways (see Fig. T3).

These pathways then may activate the transcription factors NFAT, NF- κ B, JUN, FOS (AP1), and ETS. They, in turn, activate new genes, some of which are specific transcription factors that facilitate the release of cytokines that further activate the clonal expansion of T cells. This is followed by the production of antibodies by B cell or T cell cytotoxicity. Immune memory, immune tolerance, anergy, and apoptosis are alternative functions that follow. Regulation of the development of TCR requires the cooperation of the protein tyrosine kinases (Src family), phospholipase C (PLC γ), CD5, CD28, CD48, CD80, VCP, ezrin, VAV, SHC, PtdIns, PIP2, PIP3. TCR may also regulate apoptosis of T cells. For the TCRs, there are 42 variable (V) and 61 joining (J) segments at the α chain immunoglobulin locus, and 47 V, 2 diversity (D), and 13 J segments for the β chain genes. During rearrangements, V α —J α and V β —D β —J β deletions and additions of nucleotides and dimerization may increase the variations. In blood, there appears to be $\sim 10^6$ different β chains that may combine on the average with ~ 25 different α chains. In the memory subsets, the diversity appears about 1/3 less. The number of estimated distinct TCR receptors may be 10^{12} . ▶*TCR genes*, ▶*ICAM*, ▶*LFA*, ▶*T cells*, ▶*lymphocytes*, ▶*immunoglobulins*, ▶*RAG*, ▶*Src*, ▶*Yes*, ▶*Fgr*, ▶*Fyn*, ▶*Lck*, ▶*Hck*, ▶*Blk*, ▶*Zap70*, ▶*Tec*, ▶*antibody*, ▶*MHC*, ▶*CD3*, ▶*LCK*, ▶*ITAM*, ▶*B lymphocytes*, ▶*phosphoinositides*, ▶*PIP*, ▶ $\gamma\delta$ T cells, ▶*immune system*, ▶*immunological synaps*, ▶*integrin*, ▶*signal transduction*, ▶*thymus*, and the other factors under separate entries, ▶*SLP-76*, ▶ *α -CPM*, ▶*caveolae*, ▶*ICOS*, ▶*CTLA-4*; Hennecke J, Wiley DC 2001 *Cell* 104:1; Germain RN 2001 *J Biol Chem* 276:35223; Isakov N, Altman A 2002 *Annu Rev Immunol* 20:761; Natarajan K et al 2002

Figure T2. T cell receptor in T cell function

Figure T3. A general outline of the functions of the T cell receptor (TCR) complex. Although diagrams always generalize beyond reality, they may be helpful to obtain a broad understanding. The foreign antigens are presented to the T lymphocytes either by the antigen-presenting cells or by macrophages. The macrophages are capable of partially degrading the large molecules or the invading cells. These cells associate then with either class II or class I MHC proteins, which are encoded by the HLA genes. The MHC molecules recognize the foreign antigens and bring them to the TCR and to the CD protein complex associated with the T cell surface. The class I gene products use the CD4 transmembrane proteins, whereas the class II molecules rely on CD8. The COOH ends of the TCR chains are inside the T cell's double membrane and the NH₂ end is involved in the recognition of the antigen in association with the MHC and CD elements. The TCR complex includes also the CD3 transmembrane proteins. The ζ subunit serves also as an effector in signal transduction. Protein tyrosine kinase is an important element in several signal transduction pathways. ICAM-1 on the antigen-presenting cell and LFA-1 on the CD8⁺ also cooperate in mediating the adhesion of the MHC complex. The right side of the incomplete diagram shows the association of the class II and CD4 proteins with an antigen. The other elements of this system are very similar to that shown at the left main part of the outline

Annu Rev Immunol 20:853; Werlen G et al 2003 Science 299:1859; Call ME et al 2006 Cell 127:355; <http://imgt.cines.fr/>.

T Cell, Regulatory (Treg/Tr): Regulatory T cells may disarm non-tolerant (self-reactive) naive lymphocytes (*dominant tolerance*) and bring about *infectious tolerance* of tissue grafts. These T cells occur in CD4⁺ CD25⁺ and CD4⁺ CD25⁻ cells. FOXP3 controls Treg by cooperation with NFAT. Ca²⁺ regulate NFAT

transcription factors. In activated T cells, NFAT forms co-operative complexes with AP-1. Structural mutation in FOXP3 progressively disrupts its interaction with NFAT. FOXP3 has the reduced ability to repress T cell growth factor IL-2; Treg markers CTLA4 and CD25 are upregulated. Thus, murine autoimmune diabetes is suppressed (Wu Y et al 2006 Cell 126:375). FOXP3 (Forkhead box P3; Xp11.23-q13.3) mutations involve aggressive autoimmunity mediated by regulatory T cells. Interaction of FOXP3

Figure T4. Left: Schematic representation of the T cell activation program mediated in part by the assembly of the NFAT/Fos-Jun/DNA complex on specific promoters. Right: schematic representation of the T cell tolerance program mediated in part by the assembly of the NFAT/FOXP3/DNA complex on specific promoters. Signals involved in the regulation of FOXP3 are currently unknown and indicated by ? mark. (Courtesy of Lin Chen and James stroud)

with AML1/Runx1 (acute myeloid leukemia 1/Runt-related transcription factor 1) controls Treg (Ono M et al Nature [Lond] 446:685). Mast cells are recruited by IL-9 to immune-tolerant tissues through activation by Treg and are essential for immune tolerance of allografts (Lu L-F et al 2006 Nature [Lond] 442:997). Autoimmune disease susceptibility and resistance alleles on mouse chromosome 3 (*Idd3*) correlate with differential expression of the key immunoregulatory cytokine interleukin-2 (IL-2). Reduced IL-2 production correlates with reduced function of CD4⁺ CD25⁺ regulatory T cells (see Fig. T4) (Yamanouchi J et al 2007 Nature Genet 39:329). ▶T cells, ▶autoimmune disease, ▶immune tolerance, ▶Mast cell, ▶IL-2, ▶IL-9, ▶forkhead, ▶NFAT, ▶MAP kinase [MPK], ▶AP1, ▶fos, ▶CD28, ▶T cell receptor [TCR], ▶T cells, ▶Cd25, ▶CTLA-4, ▶IL-2, ▶IL-9, ▶leukemia, ▶Runx; Graca L et al 2002 J Exp Med 195:1641; Rudensky AY et al 2006 Cell 126:253; Wan YY, Flavell R 2007 Nature [Lond] 445:766; Gavin MA et al 2007 Nature [Lond] 445:771.

T Cell Replacing Factor: A lymphokine. ▶lymphokines

T Cell Vaccination: Immunization with irradiated autologous T cells. This type of vaccination is expected to deplete circulating autoreactive T cells and has therapeutic significance for autoimmune diseases.

T Cells: Thymic lymphocytes control cell-mediated immune response (the foreign antigens are attached to them). The T lymphocytes originate in the bone marrow, differentiate in the thymus, and later migrate to the peripheral lymph nodes. While the early T cells are located in the thymus, a *negative selection* eliminates those T cells that react with self-antigens. At about the same stage of T cell development, a positive selection takes place under the influence of the MHC complex, securing the survival of those T cells that can interact with antigens associated with these cells. These encounters lead to the differentiation and activation of T cells. Cytotoxic T cells (CTL) are the major elements of the immune system; they cooperate with the natural killer cells (NK) and degrade foreign antigens with immunoproteasomes. The heterodimeric PA28a and PA28b (proteasome activating protein) activate the immunoproteasomes.

The helper T_H (CD4⁺ T cells) and the T suppressor (T_S) cells mediate the humoral (secreted) immune responses. On the surface of the T cells are the T cell surface receptors (TCR). The T_H cells stimulate the proliferation of the B (bursa) cells when they recognize their cognate antigens. The joint action of T_H cell surface receptors (TCR) and the B cell's

antigens bring about in the B cells the formation, growth, and differentiation of the proteins named lymphokines, which stimulate the propagation of B cells and the secretion of the humoral antibody. The T cell surface receptors recognize foreign antigens only if they become associated with major histocompatibility (MHC) molecules carried to the TCR by the antigen presenting cells (APC) or macrophages. The TCR links to the various intracellular signaling pathways. The activation of the T cells requires phosphorylation by SRC tyrosine kinase of the CD3 immunoglobulin chains. The activation involves co-stimulatory molecules CD28, ICAM-1, and LFA-1. For full activation, ZAP-70 protein-tyrosine kinase is also needed. The T cells are presented with a variety of antigens, including self-antigens that are carried by the APCs without discrimination. T cells distinguish self/foreign antigens. This ability begins to develop while the T cells are still in the thymus. Discrimination is a difficult task to achieve and complex phosphorylations are required for surveying the very large array of ligands of varying degree of specificity (affinity). Alternatively, it is conceivable that one peptide-MHC complex interacts first with one TCR. Then, in a contact cap this TCR detaches from the ligand, thus making possible for the ligand to bind another TCR. The process is repeated in a serial manner and assembles sufficient number of TCRs in the contact cap for productive signaling.

Chemokines enhance immunity by guiding naïve CD8⁺ T cells to sites of CD4⁺ T cell and antigen presenting dendritic cell interaction (Castellino F et al 2006 Nature [Lond] 440:890). The activation of the T cell may be only partial in case there is a subtle change (e.g., one amino acid replacement) in the peptide-MHC. The subtle variants may also inhibit the CD4⁺ helper T cells from responding to the real antigen. Altered ligands or lack of co-stimulatory signals may cause anergy of the T cell, and cannot be stimulated by the TCR but may or may not proliferate under the influence of interleukin 2 (IL2). The ligands thus can be *agonists* that fully or partially activate the T cells, or altered ligands may be weakened agonists or even *antagonists* and reduce activation. The *null ligands* provoke no response. The weak agonists may not activate ZAP-70 and may have a different pattern of phosphorylation of the CD3 ζ chain. For the fully active immune reaction, all the elements of the complex T cell activation must be in place. Some viral infections (HIV-1, hepatitis B, etc.) may lead to the production of antagonist ligands and then the cytotoxic T cells (CTL) cannot protect the body against the invader. Some aspects of the T cell activation and regulation are outlined.

On the cell membrane is the *T cell receptor* associated with CD3 and CD4 immunoglobulins. This receptor TCR mediates phosphorylation with the aid of a *protein tyrosine kinase* (PTK), *phospholipase C- γ 1*. The so activated PLC- γ 1 cleaves phosphatidylinositol-4,5 bis-phosphate (PIP2) and generates *inositol trisphosphate* (IP3) and *diacylglycerol* (DAG), which are second messengers. These second messengers activate *protein kinase C* and make available cytoplasmic Ca²⁺ for *calcineurin* (also called protein phosphatase IIB). As a consequence, the transcription factor NFAT (*nuclear factor activated T cell*) promotes the transcription of the *interleukin-2 gene*. Calcineurin also contributes to the activation of *ERK* (member of the mitogen-activated protein kinase family, MAPK). Co-stimulation is provided through the CD28 immunoglobulin system, which activates protein tyrosine kinase C that, in collaboration with the RAS G protein, stimulates the *Jun NH₂-terminal kinase* (JNK). It is also known that the *FOS* and *JUN* oncogenes contribute to the formation of the *AP* group of transcription factors, probably by acting on protein kinase C (PKC). *Phorbol myristyl acetate* (PMA) is an adjuvant for the stimulation of the *IL-2 gene*. These processes of development of effector T cells may be down-regulated when the *2E1 antibody* attaches to the *effector cell protease receptor-1*. Immunosuppressive agents such as FK506, cyclosporine, and OKT3 may cause further down-regulation.

Another important player in the T cell response is CTLA (cytotoxic T lymphocyte antigen), a molecule with about 75% homology to CD28. While CD28 is a co-stimulator of T cell activation, CTLA-4 is a negative regulator and protects against rampant lymphoproliferative disorders. The recognition of the role of CTLA offers an opportunity to neutralize its effect by specific antibodies and thereby accelerate the action of the antitumor interleukin production without serious side effects. T cell differentiation is accompanied by the appearance of surface markers in an order: CD4, CD25, CD44, CD8, and CD3. The commitment of T cell differentiation requires tumor necrosis factor- α (TNF- α) and interleukin-1 α [IL-1 α]. About 5–10% of the T cells are regulatory (T_R) and may express the CD25 activation marker. The CD4⁺ T_R cells may prevent autoimmune disease, transplant rejection, and inflammatory bowel disease (Hori S et al 2003 Science 299:1057). The understanding of these circuits may lead to designing better drugs against infections and the suppression of the rejection of tissue grafts and cancer. T Complex: The products of the virD2 and virE2 agrobacterial virulence genes associated with the 5'-end of the transferred strand of agrobacteria. ►agrobacterial virulence genes, ►T-DNA

t Complex: ►brachyury

T Cytoplasm: Texas male sterile cytoplasm of maize; almost 100% of the pollen is incapable of fertilization (sporophytic control of male sterility). ►cytoplasmic male sterility

t Distribution: ►Student's t distribution, ►t value

t Haplotype: ►brachyury

T Helper Cell: ►T_H

t Loop: ►telomeres

T Lymphocytes: ►T cells

T1 Phage: A double-stranded DNA (48.5 kbp) virulent phage, a general transducer. Only 0.2% of its cytosines and 1.7% of the adenines are methylated. The terminal redundancy is about 2.8 kb. It infects *E. coli* and *Shigella* strains. ►bacteriophages

T2, T4, and T6 Phages: T-even virulent phages that are closely related. The 166 kbp linear genome of T4 contains glycosylated and hydroxymethylated cytosine and 1–5% of its DNA is terminal redundancy; it encodes about 130 genes with known function, and about 100 additional open reading frames have been revealed. ►bacteriophages, ►development

T5 Phage (relatives BF23, PB, BG3, 29-α): The genetic material of T5 phages is linear double-stranded DNA (≈121.3 kbp) with terminal repeats (≈10.1 kbp) but without methylated bases. Three internal tracts can be deleted without loss of viability. They

are virulent phages with long tails. ▶bacteriophages, ▶development

T7 Phage (T3 is related): A virulent phage; it does not tolerate superinfection (would be required for recombination). Its 39.9 kbp genetic material is enclosed in an icosahedral head with a very short tail. It codes for about 55 genes. The T7 promoter is used in genetic vectors for in vitro transcription. Its replication requires DNA and RNA polymerase, helicase-primase complex, single-strand-binding protein, and endo- and exonuclease activities. ▶bacteriophages

θ Type Replication: θ type replication generally occurs in small circular DNA molecules starting at a single origin and following a bidirectional course (see Fig. T6). ▶replication, ▶bidirectional replication

Figure T6. Bidirectional (theta) replication

t Value (t test): The ratio of the observed deviation to its estimate of standard error: $t = \frac{d}{\sqrt{V}}$. It is used as a statistical device to estimate the probability of difference between two means. In its most commonly used form, the t is calculated as,

$$t = \frac{\bar{x}_1 - \bar{x}_2}{\sqrt{[s\bar{x}_1]^2 + [s\bar{x}_2]^2}}$$

where \bar{x} indicates the mean of the two sets of data and s stands for the standard deviation. ▶standard deviation, ▶Student's t distribution, ▶paired t test

Tachykinins: Peptides mediating secretion, muscle contraction, and dilation of veins. ▶[angiotensin](#); Labrou NE et al 2001 J Biol Chem Oct 12 Online.

Tachytelic Evolution: ▶[bradytelic evolution](#)

TACI (transmembrane activator and calcium modulator and cyclophilin ligand [CAML]): One of the TNF receptors, which regulate the expression of transcription factors NF-AT, NF- κ B, and AP-1. ▶[TNF](#), ▶[TNFR](#), ▶[TACE](#); Wang H et al 2001 Nature Immunol 2:632; Pan-Hamarström Q et al 2007 Nature Genet 39:429.

TACTAAC Box: A highly conserved consensus in mRNA introns of *Saccharomyces* yeast.

Tadpole: Amphibian (frog/toad) larva at an early developmental stage. As the tadpole matures, it loses its gills, a more pronounced tail appears, and legs develop. Subsequently, the tail is lost before the frog/toad emerges from the free-swimming larva (see Fig. T8).

Figure T8. Left: frog; right: tadpole

TAE (Tris-acetate-EDTA): ▶[electrophoresis buffers](#)

TAF: TATA box-associated factors TAF250, TAF150, TAF110, TAF60, TAF40, TAF30 α , and TAF30 β . In yeast there are promoters that require TATA box binding protein (TBP) and TAFs (i.e., they are TAF-dependent). TAFs may require TIC for efficient function. Alternatively, other promoters are independent of TAFs and require only TBP. ▶[TBP](#), ▶[TIC](#), ▶[core promoter](#), ▶[fermentation](#); Wassarman DA, Sauer F 2001 J Cell Sci 114:2895; Green MR 2000 Trends Biochem Sci 25:59.

TAF1: TAF1 subunit, TFIID carboxy-terminal kinase, activates transcription by phosphorylation of Ser³³ residue in histone H2B (Maile T et al 2004 Science 304:1010). ▶[transcription factors](#)

TAF_{II} (transcription activating factors): TAF_{II} serve as coactivators of enhancer-binding proteins. TAF_{II} appear to have sufficient homology to transcription factor TFIID that in the absence of TAF_{II} transcription

can still proceed in yeast. TFIID is actually a complex of TBP and TAFs. TAF causes a conformational change in transcription factor TFIIB. The TAF_{II}250 subunit apparently modifies the H1 histone protein to facilitate the access of the RNA polymerase to the DNA in the chromatin. The acidic activator disrupts the amino and carboxy-terminal interactions within this molecule and this results in an exposure of the binding sites for the general transcription factors to enter into a preinitiation complex with TFIIB. TFIIB initiates the formation of an open promoter complex. ▶[regulation of gene expression](#), ▶[TF](#), ▶[open promoter complex](#), ▶[transactivator](#), ▶[co-activator](#), ▶[transcription factors](#), ▶[histones](#), ▶[SAGA](#); Frontini M et al 2002 J Biol Chem 277:5841.

TAF_{II} 230/250: TAF_{II} 230/250 has histone H3, H4 acetyltransferase and protein kinase domains. The two bromodomains of the protein apparently accommodate acetyl lysines and support the activity of TFIID. The TFIID transcription complex regulates gene expression and several critical developmental processes. ▶[histone acetyltransferase](#), ▶[bromodomain](#)

TAFE (transverse alternating field electrophoresis): TAFE is used for pulsed field gel electrophoresis, when a current is pulsed across the thickness of the gel. ▶[pulsed field gel electrophoresis](#)

Taffazzin: A fibroelastin group of proteins in the muscles. ▶[Barth syndrome](#)

Tag: Large T antigen, an early-transcribed gene of SV40. It functions as an ATP-dependent helicase in the replication of the DNA. The two Tag binding sites, each, include two consensus sequences 5'-GAGCC-3', separated by six or seven A = T base pairs. In order to start replication, Tag must bind to the replicational origin, *ori*, and to neighboring sequences of the virus. ▶[Simian virus 40](#)

tag: The small t antigen of SV40, an early-transcribed gene product.

Tag1: An autonomous transposable element (3.3 kb with 22 bp inverted repeats) of (Le-) *Arabidopsis*. It is a member of the Ac (maize), Tam3 (*Antirrhinum*), and hobo (*Drosophila*) family of elements (see Fig. T9). ▶[Arabidopsis](#), ▶[retrotransposons](#), ▶[Ac-Ds](#), ▶[Tam](#), ▶[hybrid dysgenesis](#), ▶[GUS](#), ▶[gametophyte](#); Galli M et al 2003 Genetics 165:2093.

Figure T9. The *Tag1* element displays late excision during vegetative and reproductive development. When its transposase is fused to the GUS gene and transformed by such a construct, the expression (detected by the blue color) is limited to the male and female gametophytes. The illustration shows its expression in the megagametophyte. Similar is its behavior in the pollen. If however an enhancer is in its vicinity, its expression in the vegetative parts of the plants is restored. (Courtesy of Mary Galli and Nigel M. Crawford)

TAG SNP (tagSNP): A single-nucleotide(s) polymorphism characteristic for a haplotype. ▶[SNIPs](#), ▶[haplotype](#); Mueller JC et al 2005 *Am J Hum Genet* 76:387.

Tagging: Identifying a gene by the insertion of a transposon, an insertion element, a transformation vector, or by annealing with a DNA probe. These tags have known DNA sequences and can be detected on the basis of homology. When they are inserted within a structural gene or a promoter or other regulatory element of a gene, the expression of the gene may be modified or abolished. Therefore, their location may be detected by alteration in a specific function and may also assist in the isolation and cloning of the target DNA sequence. ▶[transposon tagging](#), ▶[transformation genetic](#), ▶[insertional mutation](#), ▶[probe](#), ▶[chromosome painting](#), ▶[FISH](#)

Tagmosis: The segmental organization of the insect body. ▶[homeotic genes](#); Angelini DR, Kaufman TC 2005 *Annu Rev Genet* 39:95.

Tail Bud: The tail bud gives rise to the tail of the animal from epithelial cells of the mesenchymal tailbud. Its differentiation is usually completed after the basic organization pattern of the embryo has been realized.

Tailing Homo-A: The eukaryotic mRNA generally contains a post-transcriptionally added polyA tail. Poly-A or other homopolynucleotide sequences may be added to DNAs by terminal transferases. ▶[mRNA](#), ▶[terminal transferase](#)

Tail-Less: ▶[Brachyury](#), ▶[Manx](#)

Tail-PCR (thermal asymmetric interlaced-PCR): A polymerase chain reaction resembling inverse PCR. A non-specific primer is paired with specific primers to obviate the need for circular genomic fragments. ▶[polymerase chain reaction](#), ▶[inverse PCR](#); Liu YG, Whittier RF 1995 *Genomics* 25:674.

Tailpiece, Secretory: Immunoglobulins IgM and IgA possess an 18-amino acid heavy chain C-terminal extension, and 11 of these amino residues are identical between them. This tailpiece interacts with the J chain. ▶[immunoglobulins](#), ▶[membrane segment](#); Olafsen T et al 1998 *Immunotechnology* 4(2):141.

Tajima's Method: Tajima's method statistically tests the neutral mutation theory on the basis of DNA polymorphism. D is the normalized difference of the two estimates shown.

$$D_t = \frac{\pi - \theta_s}{\sqrt{\text{Var}(\pi - \theta_s)}}$$
, where θ_s is the expected number of polymorphic sites and π is the average number nucleotide differences. ▶[mutation neutral](#); Tajima F 1989 *Genetics* 123:585.

TAM (transcription associated mutation): In TAM, the rapid rate of transcription may involve increase of mutation, apparently because translesion, nucleotide excision, or recombination may not repair the DNA damage. ▶[translesion](#), ▶[DNA repair](#), ▶[Cockayne syndrome](#)

TAM (transposable element *Antirrhinum majus*): TAM are responsible for the high mutability of genes controlling the synthesis of flower pigments, known in this plant since pre-Mendelian times. There are several TAM elements. The termini of the TAM1 and TAM2 are homologous and their insertion results in a 3 bp target site duplication. Their termini are almost identical to those of the *Spm/En* transposons of maize and somewhat homologous to the termini of the *Tgm1*

transposon of soybean. The *TAM3* transposon is different from *TAM1* and *TAM2* and 7/11 bps of its terminal repeats are homologous to the *Ac* element of maize. Both *TAM3* and *Ac* may generate 8 bp target site duplications, although *TAM3* may be flanked also by 5 bp repeats. *TAM* elements, similarly to the maize transposons, seem to move by excision and relocation. The excision is usually imprecise. The insertion within genes results in mutation and the resulting mutant phenotype depends on the site of the insertion. The excision results in more or less faithful restoration of the non-mutant phenotype depending on the extent of alteration left behind at the insertion site (see Fig. T10). ▶transposable elements plants, ▶transposons; Coen ES et al 1989 Mobile DNA. Tamarins: New world monkeys. ▶*Callithricidae*

TAMERE (trans-allelic meiotic recombination): TAMERE is mediated by a targeted mechanism involving *loxP* sites in between two markers situated in trans, i.e., in homologues pairs of chromosomes. The recombinations may result in deletions and duplications. ▶*Cre/LoxP*; Herault Y et al 1998 Nature Genet 20:381.

Tamoxifen (2-[4-{1,2-diphenyl-1-butenyl}phenoxy]-*N,N* dimethyl-ethanamine): A selective estrogen modulator drug used for the treatment of breast cancer; it may cause endometrial cancer although the benefits may outweigh the risk (Michalides R et al 2004 Cancer Cell 5:597). Tamoxifen binds to AP1 and to other estrogen response elements in

the uterus. Tamoxifen and estrogen both activate PAX2 by hypomethylation of the PAX2 promoter (see Fig. T11). This may be the cause of endometrial cancer (Wu H et al 2005 Nature [Lond] 438:981). A multigene assay has predictive value for cancer recurrence in tamoxifen-treated node-negative breast cancer (Paik S et al 2004 New Engl J Med 351:2817). ▶breast cancer, ▶raloxifene, ▶AP1, ▶estrogen receptor, ▶estrogen response element, ▶antiestrogens, ▶estradiol; Brewster A, Helzlsouer K 2001 Curr Opin Oncol 13:420.

TAN (translocation-7-9-associated *Notch* homolog): TAN is located in human chromosome 9q34. It is involved in T cell acute leukemia. ▶morphogenesis in *Drosophila* [*Notch*], ▶*Notch*, ▶leukemia, ▶T cell; Suzuki T et al 2000 Int J Oncol 17:1131.

Tandem Duplications: ▶tandem repeats

Tandem Fusion: In tandem fusion, elements are associated head-to-tail, following each other in the same direction.

Tandem Mass Spectrometry: The tandem mass spectrometry procedure selects one kind of peptide in a mixture by collision with argon or nitrogen gas. The fragments are then processed in the tandem mass spectrometer, thus obtaining the MS/MS spectrum. This analytical method has been very useful for the detection of inborn metabolic errors in small complex blood samples. ▶electrospray, ▶MALDI, ▶MS/MS, ▶proteomics; Kinter M, Sherman NE 2000 Protein Sequencing and Identification Using Tandem Mass Spectrometry, Wiley-Interscience, New York; Chace DH et al 2002 Annu Rev Genomics Hum Genet 3:17.

Tandem Repeat: Adjacent direct repeats (such as ATG ATG ATG) of any size and number. In *Caenorhabditis elegans*, 2.7% of the genome involves tandem repeats and these occur on the average once per 3.6 kb. Comparative genomic analysis of breeds of dogs and other species indicate that increase or

decrease of tandem repeats affect the apparently rapid evolution of morphological traits, particularly in the *Alx-4* (aristaless-like 4) and *Runx-2* (runt-related transcription factor) involved in skull and limb morphology, respectively (Fondon JW Garner HR 2004 Proc Natl Acad Sci USA 101:18058). ▶repeat inverted, ▶*Drosophila*, ▶runt; <https://tandem.bu.edu/cgi-bin/trdb/trdb.exe>.

Tangier Disease (HDL deficiency): Tangier disease has a human chromosome 9q22-q31 recessive phenotype caused by a deficiency of the α -I component of apolipoproteins. The afflicted individuals have enlarged orange tonsils, liver, spleen, and lymph nodes and deficiency of the beneficial high-density lipoproteins. They accumulate cholesterol in their cells because of a defect in the ABC transporter (cholesterol-efflux regulatory protein [CERP]) that normally pumps out excessive amounts of cholesterol into the low-density lipoprotein fraction. Therefore, these patients are prone to develop coronary heart disease. ▶apolipoprotein, ▶high-density lipoprotein, ▶cardiovascular disease, ▶ABC transporters, ▶HDL, ▶cholesterol, ▶SNIPS; Brooks-Wilson A et al 1999 Nature Genet 22:336; McManus DC et al 2001 J Biol Chem 276:21292.

Tankyrase (TRF1-interacting ankyrin-related ADP-ribose polymerase, 8q13): A telomere associated protein binding a negative regulator of telomere length (TRF1) through the 24 ankyrin repeats of 33 amino acids involved in binding to TRF1; at its C terminal domain it exhibits homology to poly (ADP-ribose) polymerase. TRF2 is located at 10q23.2. Tankyrase1 inhibition in human cancer cells enhances telomere shortening by a telomerase inhibitor, hastens cell death, and offers a therapeutic potential (Seimiya H et al 2005 Cell Metabolism 1:25). Upon DNA damage in humans, TRF2 is transiently phosphorylated by ataxia telangiectasia mutated locus (ATM) and in the phosphorylated state it does not bind the telomere (Tanaka H et al 2005 Proc Natl Acad Sci USA 102:15539). ▶telomere, ▶cohesin, ▶ankyrin, ▶shelterin, ▶TRF, ▶PARP, ▶ATM; Lyons RJ et al 2001 J Biol Chem 276:17172.

Tanning: The ability to produce darker skin color depends largely on the activity of the melanocyte stimulating hormone (MSH) and its receptor (MC1R). Red-haired individuals—low in these activities—do not tan easily and are susceptible to UV damage (skin cancer). ▶pigmentation in animals, ▶albinism, ▶UV, ▶melanoma, ▶melanin, ▶hair color melanocortin

TAP: (transporter associated with antigen processing, encoded by loci TAP1 [6p21.3] and TAP2 [6p21.3]

within the HLA complex): TAP delivers major histocompatibility class I molecule-bound peptides with the cooperation of β_2 microglobulin to the endoplasmic reticulum. When these peptides exit from the endoplasmic reticulum, they are carried to the T cell receptors (TCR). Mutation in TAP may prevent antigen presentation. One member of the TAP proteins is the retroviral constitutive transport element (CTE), which may mediate RNA (hnRNP, tRNA, mRNA) export from the nucleus. Efficient export, however, requires that RNA transcript would be processed within the nucleus, i.e., introns would be removed. Some retroviruses, using CTE can transport RNA. The TAP gene contains a functional CTE element in alternatively spliced intron 10 and if this is present, mammalian mRNAs can also be exported to the polyribosomes (Li Y et al 2006 Nature [Lond] 443:234). ▶HLA, ▶major histo-compatibility antigen, ▶microglobulin, ▶immune system, ▶TCR, ▶proteasomes, ▶endoplasmic reticulum, ▶RNA export, ▶hnRNP, ▶DriP, ▶REF, ▶introns; Karttunen JT et al 2001 Proc Natl Acad Sci USA 98:7431.

TAP (tandem affinity purification): A method for rapid purification of protein complexes under native conditions. A tag is affixed to either the N or C end of one of the target proteins to facilitate the process. Proteins interacting with the tags can be purified as complexes. ▶proteomics, ▶affinity purification; Puig O et al 2001 Methods 24:218; Ghammaghami S et al 2003 Nature [Lond] 425:737.

Tap: A bacterial transducer protein responding to dipeptides.

TAPA-1: A membrane-associated protein that in association with CD19 protein and the complement receptor 2 (CR2) mediates early immune reaction by the B-lymphocytes. ▶CD19, ▶CD81, ▶complement, ▶B lymphocyte, ▶immunity; Dijkstra S et al 2000 J Comp Neurol 428:266.

Tapasin: A transmembrane glycoprotein, encoded by an HLA-linked gene. Tapasin is involved with the endoplasmic reticulum chaperone, calreticulin, in processing the MHC class I restricted antigens, and in oncogenesis. ▶MHC, ▶HLA, ▶major histocompatibility complex, ▶antigen processing and presentation, ▶TAP, ▶chaperone, ▶calnexin, ▶calreticulin; Turnquist HR et al 2001 J Immunol 167:4443; Vertegaal ACO et al 2003 J Biol Chem 278:139.

Tapetum: The lining, nutritive tissue of the anther, sporangia, or other plant or animal organs (see Fig. T12). During meiosis, they may become bi- or even multinucleate cells. The presence of B chromosomes may increase these irregularities.

Figure T12. Anther cross section with tapetum colored green at left

Taphonomy: Taphonomy considers the processes of organisms becoming part of the fossil record. ► [fossil record](#)

Tapir: *Tapirus terrestris*, $2n = 80$.

Taq DNA Polymerase: A single polypeptide chain, 94 kDa enzyme that extends DNA strands 5'→3'; it has also shows a 5'→3' exonuclease activity. The enzyme is obtained from the bacterium *Thermus aquaticus*. The commercially available, genetically engineered enzyme AmpliTaq has temperature optima of 75 to 80°C. The enzyme is used for DNA sequencing by the Sanger method, for cloning, and for PCR procedures of DNA amplification. For the latter applications, it is particularly useful because during the heat denaturation cycles it is not inactivated and it is not necessary to add a new enzyme after each cycle. Phosphate buffers and EDTA are inhibitory to polymerization. ► [DNA sequencing](#), ► [polymerase chain reaction](#); Kainz P 2000 Biochim Biophys Acta 1494:23.

TaqMan (RT-PCR, real time PCR): A fluorogenic 5'-nuclease assay using a FRET probe, generally consisting of a green fluorescent dye at the 5'-end and an orange quencher dye at the 3'-end of a DNA. In a PCR process when the probe anneals to the complementary strand, the Taq polymerase cleaves the probe and the dye molecules are separated. Thus, the quencher can no longer suppress the reporter (e.g., the green dye) and a fluorescence detector can quantitate the green emission and the green fluorescence directly correlates with the yield of the PCR product. In seven minutes, sufficient quantities of DNA can be produced for the identification of pathogenic microbes. This technique may be used also for the molecular definition of deletions and SNIPs. ► [Taq DNA polymerase](#), ► [FRET](#), ► [PCR](#), ► [quenching](#), ► [SNIPs](#); Medhurst AD et al 2001 Brain

Res Mol Brain Res 90(2):125; Ranade K et al 2001 Genome Res 11:1262.

TAR (trans-activation responsive element): ► [transcription factors](#), ► [hormone response elements](#), ► [regulation of gene activity](#), ► [DNA binding proteins](#), ► [acquired immunodeficiency](#)

TAR: ► [transformation-activated recombination](#)

Tar: Bacterial chemotaxis transducer protein with aspartate and maltose being attractants and cobalt and nickel, repellents.

TAR Syndrome: ► [Robert's syndrome](#)

TARDP (TDP43, Transcription of RNA activating protein/TAR DNA binding protein, human chromosome 1p36.2): TARDP activates the long terminal repeat of the HIV-1 virus and regulates transcription of some other viruses. ► [amyotrophic lateral sclerosis](#)

Target: Anything that is the site for an action, e.g., target cell, target organ, target for DNA insertion. The target of an X-ray machine is the surface hit by the electrons, following which electromagnetic radiation is emitted in the cathode tube. ► [insertion element](#), ► [transposons](#), ► [probe](#), ► [x-rays](#)

Target Immunity (transposition immunity): As per target immunity, transposable elements usually do not insert within themselves or not even within close vicinity of an existing element. ► [insertional mutation](#)

Target Site Duplications: The insertion, transposable, and other mobile genetic elements generally make staggered cuts in the DNA where they move; on completion of the process the gaps are filled by complementary nucleotides, creating duplications at the flank (see Fig. T13).

Figure T13. Target site duplication after insertion (grey) and filling gaps

Target Theory: The target theory interprets the effect of radiations by direct *hits* on sensitive cellular targets. Physicists recognized that the amount of radiation energy delivered to living cells and causing biological (genetic) effects is extremely low and a comparable dose of heat energy would have no effect at all. Therefore, there must be certain special sensitive targets in the cells that respond highly to ionizing radiations. Studies with irradiated sperm and cytoplasm of *Drosophila* indicated that the targets are the chromosomes and the genes. These experiments in the period between 1920s and 1940s paved the way to physical inquiries into the nature of genetic material.

At this early period, it was hoped that the different radiation sensitivities among genes would permit the estimation of the size of these genes. It turned out, however, that radiation-sensitivity of the same genes varied according to the physiological stage of the tissues (higher in imbibed seeds than in dry, dormant ones) and it was higher in spermatozoa than in spermatogonia. Furthermore, temperature, genetic background, and irradiation of only the culture media of microorganisms affected radiation-sensitivity, indicating that radiation sensitivity is a more complex phenomenon and it does not precisely reveal the molecular nature of the gene. The direct action of radiation is proportional to the molecular weight of the target molecule = $(7.28 \times 10^{11})/D_{37}$, where D_{37} is the dose required to reduce the number of undamaged molecules to 37% of the initial total at a radiation dose of Gy^{-1} . DNA ($\times 10^8 \text{ mol s}^{-1}$) interacts with radiolytic products of water: $\text{OH}\cdot$ 3, $\text{H}\cdot$: 8×10^7 , e_{aq}^- (hydrated electrons): 1.4×10^8 . ▶radiation effects, ▶physical mutagens, ▶radiation indirect effects, ▶survival; Dessauer F 1954 Quantenbiologie, Springer, Heidelberg, Germany; Timofeëff-Ressovsky NW et al 1935 Nachr Ges Wiss Göttingen Math Phys Kl Biol 1:189; Lea DDA, Catchside DG 1945 J Genet 47:41.

Targeted Gene Transfer: Targeted gene transfer is used for “knockouts” ▶targeting genes, ▶knockout

Targeted Gene Trap: As per targeted gene transfer, the targeted gene flanks in the vector assures precise local insertion by homologous recombination into the gene (intron). The target promoter should be avoided. The targeting cassette contains selectable marker(s). The selectable/selected cells contain inactivated copies of the target and display the selected marker. Apparently, the efficiency of the procedure is very high, ~50% (Friedel RH et al 2005 Proc Natl Acad Sci USA 102:13188). ▶trapping promoters, ▶translational gene fusion

Targeted Mutation Recovery: In targeted mutation recovery, mutations are induced by chemical or physical mutagens. The genetic alterations are then determined by polymerase chain reaction combined with denaturing high performance liquid chromatography to distinguish between homo- and heteroduplex DNA sequences. If homozygotes were mutagenized, the presence of heteroduplexes indicates mutation at the selected locus. ▶PCR, ▶HPLC; Bentley A et al 2000 Genetics 156:1169.

Targeted Nucleotide Exchange (TNE): In TNE, a oligonucleotide sequence homologous to a gene and carrying a nucleotide that is critically different from

a single nucleotide within the gene is aligned by homology with the gene after transformation. At a low frequency, recombination may take place and the (mutant) nucleotide within the gene is replaced by the one delivered by the oligonucleotide sequence. ▶targeting genes; Liu L et al 2002 Nucleic Acids Res 30:2742.

Targeted Recombination: ▶Cre/loxP, ▶FLP/FRT, ▶targeting genes

Targeting: Aiming at or transporting to a site of some molecules. The homing of free cancer cells recognizes endothelial surfaces by their peptide markers and permits organ selectivity. ▶lymphocytes, ▶metastasis, ▶transit peptide, ▶transit signal, ▶site-specific mutagenesis, ▶mRNA targeting

Targeting Frequency: The number of insertions formed at homologous or quasi homologous site in a genome by a transforming vector.

Targeting Genes: Gene targeting can be accomplished either by insertional mutagenesis or gene replacement. *Inducible gene targeting* can be carried out by first introducing into an embryonic stem cell of a mouse by homologous recombination the gene *loxP*, to a flanking position of the desired target gene; *lox* facilitates the recognition of the sites for the *Cre* recombinase of phage P1 (see Fig. T14). Then the

Figure T14. Targeting genes

mouse is crossed with a transgenic line expressing the *Cre* recombinase under the control of an interferon-responsive cell type-specific promoter. The tissue-specific recombinase (fused to a tissue-specific promoter), thus can remove from a particular type cell the targeted gene (“floxing”). The same procedure is applicable to other eukaryotic organisms using either the phage *Cre/loxP* or the yeast *FLP/FRT* system. Since the introduction of this site-specific alteration procedure, thousands of genes have been targeted, and in mouse alone several thousand targeted stocks have been generated. Lately gene targeting became one of the most powerful tools in genetic analysis of eukaryotes. The general principles of the procedures are illustrated. By gene targeting through double crossover within the flanking chromosomal region, different copies of the gene can be inserted (replaced) or the gene can be placed under

Figure T15. Target replacement by homologous recombination

the control of a specific endogenous or foreign promoter (see Fig. T15).

Targeting mammalian genes is feasible but the efficiency is fairly low (10^{-2} to 10^{-5}) compared to embryonic chicken stem cells (ES). In the transfection of avian leukosis virus (ALV)-induced chicken pre-B cells, the efficiency of recombination between the exogenous DNA and target locus may be as high as 10 to 100%. When a single mammalian chromosome is transferred to chicken cells by microcell fusion, in the somatic hybrid cell the recombination proficiency of the mammalian chromosome at the selected locus may increase up to 10–15%. The recombined chromosome can then be shuttled back to mammalian cells for analysis.

Another targeting procedure takes advantage of the bacterial tetracycline repressor gene that attaches to the promoter of some genes and keeps them silent unless tetracycline is applied that binds to the repressor; by inactivating it the genes are turned on. When this prokaryotic tetracycline repressor gene is inserted into a murine activator gene by transformation, the activator is incapacitated and the gene silenced. Alternatively, by inserting the tetracycline suppressor into a viral activator gene, all the genes of the transgenic mice that recognize the tetracycline suppressor—activator construct are turned on in the absence of tetracycline. On adding tetracycline to such a system, the antibiotic combines with the repressor—activator in the hybrid construct and the genes are now shut off because the suppressor—activator construct is removed from the activation position. Such a targeting construct can thus be used for on/off switching of particular genes. The success of targeting may be increased if the vector is an RNA-DNA hybrid molecule that pairs more efficiently with the target. By the PCR targeting procedure, a 20 bp DNA sequence tag may be generated using the photolithography procedure and DNA chips. The tag sequences are as different as possible, yet possess hybridization properties to be identified simultaneously on high-density oligonucleotide arrays. Genomic DNA is isolated from a pool of deletions tagged and used as templates for amplification. For

selectability, a resistance gene (aminoglycoside phosphotransferase) may be used. The targeting sequence is amplified by PCR that have primers at the 3'-end homologous to the marker and at the 5'-end homologous to the target. This system is introduced into the cells by transformation. After homologous recombination at two flanks of the targeted open reading frame, the target is replaced by a construct including the 20-base tag, the selectable marker, and the deletion mutation sequence (see Fig. T16).

Figure T16. In *Drosophila* gene targeting can be achieved by “ends-in” (upper part of the diagram) and by “ends-out” (lower part of the diagram) procedures. The lower diagram indicates that parts of the 3' and 5' sequences of the target are deleted by the recombination. The requisites are (i) expressing a site-specific recombinase transgene, (ii) a transgene expressing a site-specific endonuclease, and (iii) a transgenic donor construct carrying recognition sites for both enzymes and the DNA of the locus targeted. This gene targeting mutates genes, which are not known by function but only by sequence. (Modified after Rong YS, Golic KG 2000 Science 288:2013)

The large number of tagged deletion strains can then be pooled and tested under a variety of conditions to test how deletion affects the function of the gene. The molecular tags are amplified and

hybridized to a high-density array of known oligonucleotides, complementary to the tags. The relative intensity of hybridization reveals the relative proportion of the individual deletion strains in the pool and their fitness. Phenotypic methodological and other relevant information is contained in the TBASE <http://www.jax.org/>. Chimeric, site-specific nucleases when used with appropriate nuclear localization signals, greatly enhance targeting by the generation of double-strand breaks in the human somatic cells (Porteus MH, Baltimore D 2003 Science 300:763; Bibikov M et al 2003 Science 300:764). A precisely placed double-strand break induced by engineered zinc finger nucleases (ZFNs) can stimulate integration of long DNA stretches into a predetermined genomic location, resulting in high-efficiency site-specific gene addition. Using an extrachromosomal DNA donor carrying a 12 bp tag, a 900 bp ORF, or a 1.5 kb promoter-transcription unit flanked by locus-specific homology arms, we find targeted integration frequencies of 15%, 6%, and 5%, respectively, within 72 h of treatment, and with no selection for the desired event. Importantly, we find that the integration event occurs in a homology-directed manner and leads to the accurate reconstruction of the donor-specified genotype at the endogenous chromosomal locus, and hence presumably results from synthesis-dependent strand annealing repair of the break using the donor DNA as a template. This site-specific gene addition occurs with no measurable increase in the rate of random integration. Remarkably, we also find that ZFNs can drive the addition of an 8 kb sequence carrying three distinct promoter-transcription units into an endogenous locus at a frequency of 6%, also in the absence of any selection (Moehle EA et al 2007 Proc Natl Acad Sci USA 104:3055). Gene targeting should be extended to any animal in which embryonic stem cells can be successfully managed. Unfortunately, this has not been realized with the majority of mammals, with the exception of mice and sheep. An alternative approach by nuclear transplantation appears more practical (Kubota C et al 2000 Proc Natl Acad Sci USA 97:990). Initially, the success of gene targeting in plants was generally in the 10^{-4} – 10^{-3} range but this has been greatly improved recently. Locus-specific deletions (52 to 1 bp), which were meiotically transmissible, could be obtained in *Arabidopsis* plants by generating double-strand breaks with the aid of zinc-finger nucleases (Lloyd A et al 2005 Proc Natl Acad Sci USA 102:2232). When the promoterless GFP (green fluorescent protein) gene was inserted into the *CRUCIFERIN* seed protein gene of *Arabidopsis* and it acquired the functional promoter, the expression of the green fluorescence could be easily detected in the large seed-output of the plants. In plants transgenic for the yeast chromatin-remodeling

and recombination-promoting protein gene, RAD54, the success of targeting increased from 10^{-2} to 10^{-1} and could be readily detected by capturing the promoter in the Cruciferin-GFP fusion protein (Shaked H et al 2005 Proc Natl Acad Sci USA 102:12265).

Actually, the INO80 protein encoded in *Arabidopsis* also displays an effect similar to Rad54 (see Fig. T17) (Fritsch O et al 2004 Mol Cell 16:479). ▶insertional mutation, ▶GAMBIT, ▶local mutagenesis, ▶gene replacement, ▶RMCE, ▶knock-out, ▶homologous recombination, ▶site-specific recombination, ▶ends-in ends-out recombination, ▶adeno-associated virus, ▶gene therapy, ▶chromosomal rearrangement, ▶homing endonucleases, ▶chromosome uptake, ▶IRES, ▶photolithography, ▶DNA chips, ▶RNA double-stranded, ▶RNAi, ▶Cre/loxP, ▶Flp/FRT, ▶GMO, ▶nuclear transplantation, ▶conditional targeting, ▶RID, ▶TFO, ▶targeted nucleotide exchange, ▶MICER, ▶gene targeting, ▶trapping promoters; Thomas KR et al 1986 Cell 44:419; Sauer B 1998 Methods 14:381; Vasquez KM et al 2001 Proc Natl Acad Sci USA 98:8403; Rong YS et al 2002 Genes Dev 16:1568; a historical account of targeting complex disease genes: Smithies O 2005 Nature Rev Genet 6:419.

Targeting Physiological: Physiological targeting locates regulatory factors to the appropriate intracellular site. Protein domains may control these functions and may be hampered by chromosomal translocation and gene fusion.

Targeting Proteins: ▶two-hybrid system, ▶one-hybrid binding assay, ▶three-hybrid system, ▶microcalorimetry, ▶surface plasmon resonance, ▶gel retardation, ▶gel filtration, ▶immunoprobe, ▶immunolabeling, ▶prenylation, ▶myristic acid; Fischer W et al 2001 Infect Immun 69:6769.

Targeting Signal: ▶signal peptide, ▶signal sequence, ▶signal sequence recognition particle

Targeting, Transcriptional: Transcriptional targeting is generally directed to the enhancer/promoter area of a specific gene. The goal is to avoid non-specific genes that may have deleterious consequences. (See Sadeghi H, Hitt MM 2005 Curr Gene Ther 5:411; Izumo T et al 2007 Int J Oncol 31:379).

Targeting Vector: In a viral vector, a section of the envelope protein gene is replaced by the coding sequences of, e.g., 150-amino acids of erythropoietin (EPO) and thus, the replacement improves its ability to recognize the EPO receptor. Other approaches involve pseudotyping or attaching special ligands to the envelope (Müller OJ et al 2003 Nature Biotechnol 21:1040). Liposomal vehicles may be conjugated with special antibodies for target recognition. Bifunctional antibodies that recognize both viral epitopes and target cell antigens have been constructed. Another approach was found to covalently link biotin to recombinant adenovirus. The Kit receptor and the stem cell factor (SCF) were then linked through an avidin bridge to the target to assure the proper tropism. It is highly desirable that ligand–receptor pairs be limited to specific functions rather than cross over to members of regulatory networks. Such a goal can be reached by stepwise, individual, site-specific saturation mutagenesis followed by phenotypic screening based on the yeast two-hybrid system. The nuclear hormone estrogen receptor so modified can favor a synthetic 4,4'-dihydroxybenzil by more than a million-fold over the natural ligand 17 β -estradiol. Such a technique can specifically target human endometrial cancer (Chockalingam K et al 2005 Proc Natl Acad Sci USA 102:5691). ▶liposome, ▶vectors, ▶pseudotyping, ▶magic bullet, ▶gene therapy, ▶KIT oncogene, ▶stem cell factor, ▶biotin, ▶avidin, ▶epitope, ▶dihydroxybenzil, ▶nuclear receptor, ▶estradiol, ▶estrogen receptor, ▶targeting transcriptional; Peng KW et al 2001 Gene Ther 8:1456; Yu D et al 2001 Cancer Gene Ther 8:628; therapeutic applications: Waehler R et al 2007 Nature Rev Genet 8:573.

Target-Primed Reverse Transcription: Retrotransposons without long terminal repeat sequences are inserted into eukaryotic genomes by a process in which cleaved DNA targets are used to prime reverse transcription of the RNA transcript of the element. ▶LINE, ▶reverse transcription

TART: A telomere-specific retroposon of *Drosophila* with an about 5.1-kb 3'-non-coding tract, which is homologous to HeT-A; it also encodes a reverse transcriptase. ▶telomere, ▶Het-A, ▶LINE, ▶retroposon, ▶reverse transcription; Haoudi A, Mason JM 2000 Genome 43:949.

Tarui Disease: ▶glycogen storage diseases (Type VII)

TAS (termination associated sequences): Signals for ending transcription. Also, telomere-associated sequences involved in the silencing of genetic functions. ▶transcription, ▶telomere, ▶silencing

tasiRNA: Transacting siRNA produced by Dicer4. ▶Dicer, ▶RNAi, ▶siRNA

Tasmanian Devil (*Sarcophilus harrisii*, $2n = 12 + XY$): Australian, large, black, white-spotted, carnivorous marsupial frequently with large tumors on its face (⇒) that generally become fatal because the animals cannot feed (see Fig. T18). Tissue fragments acquired during fighting with infected individuals probably transmit the tumors. In the tumor cells in each of the 11 animals examined, the sex chromosomes, a pair of chromosome 2, one chromosome 6, and one arm of chromosome 1 were missing, but four chromosomes of unidentified origin were added so the tumor cells had 13, rather than the normal 14 chromosomes (Pearese A-M, Swift K 2006 Nature [Lond] 439:549; Owen D, Pemberton D 2006 Tasmanian Devil: A Unique and Threatened Animal. Natural History Museum, Allen & Unwin. London, UK; McCallum H, Jones M 2006 PLoS Biol 4(10): e342). ▶canine transmissible venereal tumor

Figure T18. Tasmanian devil

Tassel-seed: Mutations (*ts*) in maize result in kernels on the normally male inflorescence (tassel) as a result of the effemination. ▶sex determination

Taste: Taste is controlled by a signal transducing G protein, gustducin. Both bitter sweet and unamintasting is mediated by gustducin. Ionic stimuli of salts and acids interact directly with ion channels and depolarize taste-receptors. Sugars, amino acids, and most bitter stuff bind to specific receptors outside the cell membrane and these are then connected to G proteins. It is assumed that gustducin is involved with a phosphodiesterase. Phospholipase C also appears to play a role in the taste circuits. Gustducin receptors are present in the tongue and also in the stomach and the intestines. Taste buds are only a few

thousand in number, with 3 to 5×10^4 taste receptors. The TRPM cation channel family greatly enhances sweet perception at temperatures between 15°C and 35°C (Talavera K et al 2005 Nature [Lond] 438:1022). A locus in human chromosome 5p15 was associated with sensing the bitter taste of 6-n-propyl-2-thiouracil. The phenylthiocarbamide taste locus (PTC/PROP) is a receptor, TAS2R, located in human chromosome 7q. There is great variation among the TASR genes. Some individuals, however, fail to identify its bitter taste. Seven transmembrane domain taste receptor sequences were attributed to clusters also in human chromosomes 7q31-q32 and 12p13. The T1R-1/TAS1R taste receptor gene (1p36) family is apparently specific for sweetness, whereas T1R2 for bitter taste. The latter may include 50–80 genes. Mammals can taste sour, salty, sweet, bitter, and umami (monosodium glutamate). Genes for different taste receptors have been isolated. A distinct and separate sour taste receptor is PKD2L1 (polycystic kidney disease-like ion channel; Huang AL et al 2006 Nature [Lond] 442:934). ▶ion channels, ▶degenerin, ▶signal transduction, ▶olfactogenetics, ▶fragrances, ▶phenylthiocarbamide; Dulac C 2000 Cell 100:607; Nelson G et al 2001 Cell 106:381; Lindemann B 2001 Nature [Lond] 413:219; Margolske RF 2002 J Biol Chem 277:1; Bufe B et al 2002 Nature Genet 32:397; brain circuits of bitter and sweet: Sugita M, Shiba Y 2005 Science 309:781; Drayna D 2005 Annu Rev Genomics Hum Genet 6:217; mammalian taste receptors: Chandrashekar J et al 2006 Nature [Lond] 444:288.

TAT (twin-arginine translocase): A ~600 kDa protein complex that moves proteins through thylakoid and prokaryotic membranes. ▶thylakoid; Robinson C, Bolhuis A 2001 Nature Rev Mol Cell Biol 2:350.

Tat: 14 kDa primary regulator of the HIV virus. ▶acquired immunodeficiency

Tat1: A transposon-like element (431 bp) in *Arabidopsis*, flanked by 13 bp inverted repeats and 5 bp target-site duplications, but without any open reading frame and thus incapable of movement by its own power. There is also a Tat1 human sulfate transporter and TAT 1 and TAT2 yeast amino acid permeases. ▶Arabidopsis, ▶transposons, ▶open reading frame; Peleman J et al 1991 Proc Natl Acad Sci USA 88:3618; Toure A et al 2001 J Biol Chem 276:20309; Schmidt A et al 1994 Mol Cell Biol 14:697.

TAT-GARAT: The TAATGARAT enhancer motif of Herpes simplex virus. ▶cigar

TATA Box: Thymine (T) and adenine (A) containing binding sites for transcription factors and the RNA polymerase complex. The bases, their numbers, and

the exact base sequences in the TATA boxes vary. In yeast, the TATA box is 40–120 bp, in the majority of other eukaryotes 25–30 bp ahead of the transcription initiation site (Struhl K 1989 Annu Rev Biochem 58:1051). Many housekeeping genes and the RAS oncogene do not have this sequence (Suzuki Y et al 2001 Genome Res 11:677). In case of the absence of TATA, some other A and T nucleotides may associate with the TATA-box-binding proteins (TBP). A downstream promoter element (DPE) has also been identified. DPE may bind TFIID. In *Drosophila*, some core promoters have both TATA box and DPE or only one of the two (Kutach AK, Kadonaga JT 2000 Mol Cell Biol 20:4754). ▶Pribnow box, ▶Hogness (Goldberg) box, ▶transcription factors, ▶transcription complex, ▶open promoter complex, ▶asparagine synthetase, ▶core promoter, ▶promoter, ▶TBP, ▶PWM, ▶DPE; Smale ST, Kadonaga JT 2003 Annu Rev Biochem 72:449.

TATA Box Binding Protein: ▶TBP

TATA Factor (TF): ▶transcription factors, ▶TATA box

TATA Inr: Core promoters may or may not contain these pyrimidine-rich transcription initiator elements. ▶TATA box, ▶open promoter complex, ▶transcription factors, ▶core promoter

Tatsumi Factor: A blood-clotting factor required for the activation of Christmas factor by activated PTA. It is controlled by an autosomal locus. ▶antihemophilic factors, ▶blood clotting pathways, ▶PTA deficiency disease, ▶hemostasis

TAU (MAPT, 17q21.1): The size of the tau gene can vary from ~352 to 441 amino acids in the isoforms of the microtubule-associated proteins by alternative splicing of the mRNA (Margittai M, Langen R 2004 Proc Natl Acad Sci USA 101:10278).

By reducing motor reattachment rates, tau affects cargo travel distance, motive force, and cargo dispersal. Different isoforms of tau, at concentrations similar to those in cells, have dramatically different potency.

These defined mechanism show how altered tau isoform levels could impair transport and thereby lead to neurodegeneration without the need of any other pathway (Vershinin M et al 2007 Proc Natl Acad Sci USA 104:87). It seems to form tangles by virtue of the $^{306}\text{Val-Gln-Ile-Val-Tyr-Lys}^{311}$ motif in the 6 tau monomers in several types of nerve degenerative diseases (e.g., Pick disease, Alzheimer disease, progressive supranuclear palsy, corticobasal degeneration).

A pseudogene exists at 6q21. Base substitution and splice site mutations may lead to Pick disease, parkinsonism and Alzheimer's disease. In the tangle

of the paired helical filaments, tau is hyperphosphorylated causing defects in microtubule assembly and mitotic arrest. The use of a kinase inhibitor (at lysine 252) can prevent hyperphosphorylation of tau and the aggregation of tau without reducing the tangles; such a treatment reduces severe motor function impairment in transgenic mice indicating that aggregation rather than tangling is the cause of the development of tau pathology (Le Corre S et al 2006 Proc Natl Acad Sci USA 103:9673).

The adverse effect of hyperphosphorylation may be prevented by trimethylamine N-oxide (TMAO) because this natural compound lowers the concentration of tubulin needed for assembly. The hyperphosphorylated tau may self-assemble and the causes the fibrillary tangle observed in the degenerated brain of Alzheimer's patients. Cyclic-AMP-dependent protein kinase (PKA), glycogen synthase kinase 3 β (GSK-3 β), or Cdk5 may carry out the phosphorylation.

Phosphorylation of a Ser or a Thr amino acid preceding a Pro creates a binding site for the prolyl-isomerase Pin1. When Pin1 binds to this site in tau, it may deplete it in the brain leading to some of the problems related with Alzheimer's disease. Amyloid- β immunotherapy can clear the fibrillar tangle with the aid of proteasomes, if applied before the hyperphosphorylation of tau (Oddo S et al 2004 Neuron 43:321). In human Parkinsonism, mutation can affect aberrant splicing of exon 10. Using a spliceosome-mediated trans-splicing, the mRNA can be reprogrammed. Thus, creating a new exon 9–exon 10 junction indicates the feasibility of therapeutic trans-splicing (Rogriguez-Martin T et al 2005 Proc Natl Acad Sci USA 102:15659). Neurofibrillary degeneration is increased when both A β and tau are expressed the same time. In a mouse model of Alzheimer's disease, the chronic supply of nicotine exacerbates tau tangles (Oddo S et al 2005 Proc Natl Acad Sci USA 102:3046). In mouse transgenic for a suppressible tau, memory was recovered and neuron numbers were stabilized after suppression of tau, yet neurofibrillary tangles continued to grow, indicating that the tangles are not sufficient to account for the degenerative phenomena (see Fig. T19) (SantaCruz K et al 2005 Science 309:476). Fragments of the repeat domain of tau, containing mutations of FTDP17 (frontotemporal dementia with Parkinsonism linked to chromosome 17 also called Pick disease), produced by endogenous proteases, can induce the aggregation of full-length tau. Fragments are generated by successive cleavages, first N-terminally between lysine257 and serine258, then C-terminally around residues 353–364; conversely, when the N-terminal cleavage is inhibited, no fragmentation and aggregation takes place. The C-terminal truncation and the

Figure T19. Transgenic mouse brain expressing neurofibrillary tangle (enlarged in insert) and A β plaques similar that occurs in humans afflicted by Alzheimer disease. (Courtesy of Drs. Dennis W. Dickson and Wen-lang Lin, Mayo Clinic, Jacksonville, Florida; I am indebted also to Mike Hampton, Maryland)

coaggregation of fragments with full-length tau depend on the propensity for β -structure. The aggregation is modulated by phosphorylation but does not depend on it. Aggregation but not fragmentation is toxic to cells; conversely, inhibiting either aggregation or proteolysis can prevent toxicity (Wang YP et al 2007 Proc Natl Acad Sci USA 104:10252). In a *Drosophila* model of tauopathy, neurodegenerative symptoms appeared without the fibrillary tangle. ▶FTDP-17, ▶prion, ▶amyloids, ▶secretase, ▶sirtuin, ▶Pick disease, ▶Alzheimer disease, ▶p35, ▶parkinsonism, ▶microtubule, ▶CDK, ▶palsy, ▶corticobasal degeneration, ▶synuclein, ▶RNAi, ▶trans-splicing; von Bergen M et al 2000 Proc Natl Acad Sci USA 97:5129; Wittmann CW et al 2001 Science 293:711; Lewis J et al 2001 Science 293:1487; Liou Y-C et al 2003 Nature [Lond] 424:556.

Taurine ($\text{H}_2\text{N}-\text{CH}_2-\text{CH}_2-\text{SO}_3\text{H}$): An amino acid absent from muscle proteins but present in several body fluids (it was first isolated from the bile of cattle [*Bos taurus*]; hence the name). It is important for membrane transport and as an antioxidant and is thus an essential nutrient. In its absence from the tRNA, Leu^{UUR} (5-taurinomethyluridine) may cause mitochondrially-determined disease. ▶mitochondrial disease

Tautomeric Shift: The reversible change in the position of a proton in a molecule, affecting its chemical properties; it may trigger base substitution and thus

mutation in DNA. ▶hydrogen pairing, ▶enol form, ▶substitution mutation; Watson JD, Crick FHC 1953 Cold Spring Harbor Symp Quant Biol 19:123.

TAX1: A human T-cell leukemia virus (40 kDa) protein gene (1q32.1) with three 21 bp CRE-like sites; it increases DNA binding of transcription factors containing a basic leucine zipper domain. ▶leucine zipper, ▶leukemia, ▶CRE, ▶CREB, ▶HTLV; Soda Y et al 2000 Leukemia 14:1467.

Taxol (Paclitaxel): A spindle fiber blocking natural substance isolated from the yew *Taxus brevifolia*; it is a carcinostatic and radio-sensitizing drug. It induces apoptosis. ▶spindle, ▶carcinostasis, ▶epothilone, ▶microtubule, ▶apoptosis, ▶Herceptin, ▶Abraxane; Okano J-i, Rustgti AK 2001 J Biol Chem 276:19555; Jennewein S et al 2001 Proc Natl Acad Sci USA 98:13595; Ganesh T et al 2004 Proc Natl Acad Sci USA 101:10006; 19 proteins involved in taxol synthesis: Jennewein S et al 2004 Proc Natl Acad Sci USA 101:914.

Taxon (plural taxa): The collective name of taxonomic categories.

Taxonomy: (biological) classification with a number of different systems. The bases of this classification are morphology, anatomy, genetics, biochemistry, physiology, cytology and macromolecular structure (DNA, RNA and proteins). Generally, five broad categories are recognized: prokaryotes and viruses, protists, fungi, plants, and animals. The taxonomic categories of eukaryotes include Phylum, Class, Order, Family, Genus, Species, and Subspecies (such as varieties, cultivars, breeds). In the past, the classification was more rigid because the species was considered the mark of genetic isolation. Today, with somatic cell hybridization and transformation (transfection) there is no limit to genetic exchange between various categories. There are over 300,000 plant and over 1,000,000 animal species named and classified by rules of nomenclature. For naming, binomial nomenclature is used. The capitalized first letter of the first name identifies the genus and the species is designated by the second name in lower case letters. This is sometimes followed by the name of the first taxonomists who classified the organisms, e.g., *Arabidopsis thaliana* (L.) Heynh., indicating *Arabidopsis* as the genus, *thaliana* as the species, L. stands for Linnaeus and Heynh. is the abbreviation for Heynhold who suggested the current name. Plant taxonomy: <http://www.itis.gov/>; virus taxonomy: <http://www.ncbi.nlm.nih.gov/ICTVdb>; NCBI taxonomy database: <http://0-www.ncbi.nlm.nih.gov.library.vu.edu.au/Taxonomy/>. taxonomyhome.html; sequence database: <http://www.ebi.ac.uk/seqdb/Projects.html>.

Tay-Sachs Disease: One of the most thoroughly studied biochemical diseases in human populations; it is controlled by an autosomal recessive gene (see Fig. T20). This defect occurs in all ethnic groups, but it is particularly common among Ashkenazi (eastern European) Jews where the

Figure T20. Cherry-red spot on the macula in Tay-Sachs disease

frequency of the gene is approximately 0.02 and the frequency of heterozygotes may be over 3%. The prevalence is about 1/2,500 to 1/5,000 per birth. Among the Sephardim Jews and other ethnic groups, the frequency is about 1/1,000,000. Since the afflicted individuals generally die by age three to four, the high frequency indicates that some heterozygote advantage must have existed for this gene. The effective genetic screening for heterozygotes in the USA has greatly reduced the prevalence of this disease (Kaback MM 2001 Adv Genet 44:253). The onset is at six months when general weakness, extension of the arms in response to sounds, a scared look, and muscular stiffness and retardation appear in an earlier apparently normal child. Then in rapid succession, paralysis, reduction of mental abilities, and vision problems leading to blindness become evident. One characteristic symptom is a cherry-red spot (↓) on the macula (gray opaque part of the cornea [eye]), caused by cell lesions. All these symptoms are the results of a deficiency of β -hexosaminidase enzyme α subunit that controls the conversion of ganglioside G_{M2} into G_{M3} . As a consequence, G_{M2} ganglioside accumulates leading to degeneration of the myelin of the nervous system. Hexosaminidase A is composed of the α subunits (human chromosome 15q23-q24) and hexosaminidase B is a multimer of

the β subunits (human chromosome 5q13). Sandhoff's disease involves both hexosaminidase A and B deficiencies or only hexosaminidase B deficiency, and has somewhat similar symptoms with more rapid progression. Another (Type 3), milder form of GM₂ gangliosidosis (5q31.3-q33.1) with some hexosaminidase A activity may permit survival up to age ~15. In a mouse model, *N*-butyldeoxynojirimycin prevents the accumulation of GM₂. In Sandhoff's disease model mouse, stereotactic (precisely positioned) brain injection by adeno-associated virus vector containing the α and β subunits of the human β -hexosaminidase gene, including also the tat sequence of the HIV virus (for enhancing protein expression and distribution), resulted in the transgene being expressed and consequently GM₂ ganglioside storage and inflammation being reduced. The survival of the animals expanded to more than twice as long, to over a year, and motor function was restored, indicating that this type of gene therapy may be eventually applicable for this incurable human disease (Cachón-Gonzalez MB et al 2006 Proc Natl Acad Sci USA 103:10373).

The older common name of these gangliosidoses was amaurotic familial idiocy. ▶Sandhoff's disease, ▶hexosaminidase, ▶gangliosidoses, ▶gangliosides, ▶sphingolipids, ▶lysosomal storage disease, ▶genetic screening, ▶Jews and genetic disease, ▶gene therapy; Mahuran DJ 1999 Biochim Biophys Acta 1455:105; Myerowitz R et al 2002 Hum Mol Genet 11:1343.

Tay Syndrome: ▶trichothiodystrophy

T-Bam: Same as CD40 ligand.

T-Band: The telomeric regions of chromosomes with the highest concentrations of genes and G + C in the genome. ▶band, ▶chromosome banding, ▶isochores

T-bet (T-box expressed in T cells): A 530-amino acid transcription factor that promotes the differentiation and activity of T_H1 cells and represses the formation of T_H2 lymphocytes. The repression of T_H2 is brought about by tyrosine kinase-mediated interference of GATA-3 binding to its target DNA (Hwang ES et al 2005 Science 307:430). T-bet deficiency reduces atherosclerosis in mice (Buono C et al 2005 Proc Natl Acad Sci USA 102:1596). T-bet is aided by CpG DNA oligonucleotides in innate immunity (Lugo-Villarino G et al 2005 Proc Natl Acad Sci USA 102:13248). ▶T_H, ▶T box, ▶GATA, ▶omesodermin, ▶innate immunity, ▶memory immunological; Mullen AC et al 2001 Science 292:1907; Lovett-Racke AE et al 2004 Immunity 21:719.

TBL1: transducin-beta-like protein. ▶transducin; Tomita A et al 2004 Mol Cell Biol 24:3337.

TBP (TFII τ): TATA box binding protein is a subunit of the general transcription factors, TFIID, SL1, and TFIIB proteins that bind to DNA like a saddle in a two-fold symmetry (see Fig. T21) (Burley SK, Roeder RG 1996 Annu Rev Biochem 65:769). The TFIIB complex shares amino-terminal homology with TFIIB. TFIIB has anti-parallel β sheets at the concave area where it forms a reaction with the special A and T rich sequence of the DNA. TFIIB-related factor (Bref1) at the carboxy-terminal mediates the binding of TBP to the DNA. The convex surface provides opportunities for interaction with other proteins. The TBP is highly conserved among different organisms from yeast to the plant *Arabidopsis* to mammals. TBP may form a complex with several TAF proteins. It apparently nucleates the pre-initiation complex of all three DNA-dependent RNA polymerases—pol I, II, and III—but in a somewhat different manner (Fan X et al 2005 Nucleic Acids Res 33:838). The TBF-like factors (TLFs) variously denoted as

Figure T21. TBP—TATA box schematic representation. TBP of *Arabidopsis* recognizes the minor groove of TATAAAAG

TRF2 or TRP are orthologs of TFL and appear functionally different from TBP. TLF appears to be required for differentiation and is needed for the transcription of some special sets of genes. The TBP may also bind SL1 transcription factor of pol I but this binding is exclusively either with TFIID or SL1. The pol III TBP complex is called TFIIB. The Dr1 repressor binds to TBP and selectively inhibits pol II and pol III action but pol I is not affected, however, because when pol II and III are repressed the relative output of pol I appears higher. The TFIID complex activity is restricted by the nucleosomal organization of the chromatin. The C-terminus of TBP is highly conserved, whereas the N region displays great variations. In TBP^{-/-} mouse cells, DNA-dependent RNA polymerase II seems functional but pol I and pol III are arrested. ▶transcription factors, ▶pol, ▶TAF; Berk AJ 2000 Cell 103:5; Magill CP et al 2001 J Biol Chem 276:46693; Zhao X, Herr W 2002 Cell 108:615; Martianov I et al 2002 Science 298:1036.

TB-parse: A program for the identification of protein-coding sequences. (See Nucleic Acids Res 22:4768).

TBR: Transforming growth factor receptors. ►TGF

Tc: A family of transposons in *Caenorhabditis*. *Tc1* is silenced in the germline by a natural RNAi (Sijen T, Plasterk RHA 2003 Nature [Lond] 426:310). ►transposon, ►*Caenorhabditis elegans*

TC4: A small nuclear G protein with CD28 being its primary ligand. It is involved in the regulation of T lymphocytes. ►G proteins, ►RAN; Nieland JD 1998 Cancer Gene Ther 5:259.

TC Motif: ►AP1, ►AP2, ►transcription factors

TCC (terminal complement complex): TCC includes C5b-9, C5b-8, and C5b-7 complement components involved in the complement-mediated killing of foreign cells. ►complement, ►immune system

TCC (transitional cell carcinoma): See Dal Cin P et al 1999 Cancer Genet Cytogenet 114(2):117.

TCCR (T cell cytokine receptor): TCCR mediates adaptive immune response of T_H1 lymphocytes. (See Chen Q et al 2000 Nature [Lond] 407:916).

TCF (ternary complex factors): TCF are co-activators of transcription such as Elk, Sap-1a, Sap-1b, ERP-1, and other members of the ETS family of transcription factors and oncoproteins. Some are members of the high mobility group proteins. TCF usually binds to the AACAAAG sequences of the promoter. In case of defect in the tumor suppressor APC gene (adenomatous polyposis) and/or in the β -catenin gene, Tcf-4 (responsible for crypt stem cells) is activated and malignancy may result. TCF4 when interacting with phosphorylated Jun regulates intestinal cancer (Nateri AS et al 2005 Nature [Lond] 437:281). CBP seems to be a repressor of TCF. ►high mobility group proteins, ►ETS, ►CBP, ►Gardner syndrome, ►melanoma, ►LEF, ►catenins, ►mtTAF, ►CBP, ►Wingless; Morin S et al 2001 Mol Cell Biol 21:1036.

TCGF: ►interleukin 2, ►IL-2

TCID₅₀: Tissue culture infective dose causing (viral) infection to 50% of the cells.

Tcl: ►hybrid dysgenesis

TCL1: An oncogene (14q32.1). It is normally expressed in fetal thymocytes, in pre-B, and immature B cells and weakly in CD19⁺ peripheral blood lymphocytes. Chromosomal translocations or inversions near the enhancer element of TCR may cause leukemia or lymphoma. It enhances the Akt kinase activity and promotes nuclear transport. ►B lymphocyte, ►CD19, ►TCR, ►leukemia, ►lymphoma, ►Akt; Pekarsky Y et al 2001 Oncogene 20:5638.

TCLo: Toxic concentration low; the lowest concentration of a substance in air that produces toxic, neoplastic, and carcinogenic effects in mammals.

t-Complex: The t-complex of mouse consists of six complementation groups in chromosome 17, affecting tail development and viability. Homozygous mutants, of the same complementation group, are generally lethal. ►brachyury

TCP-1 (CCT): The cytoplasmic α subunit chaperonin coded for by the t-complex in mouse chromosome 17. Its homolog occurs also in the pea leaf cytosol. A TCP protein has been suggested to mediate the curvature of the leaf surface of crinkly mutations (Nath U et al 2003 Science 299:1404). ►chaperonins, ►chaperone, ►brachyury

Tcp20: Synonymous with CCT ζ and Cct6. ►chaperonins; Li WZ et al 1994 J Biol Chem 269:18616.

TCR Genes: The T cell receptors are glycoproteins and are similar to the antibody molecules. The TCR α chain has variable (V), diversity (D), junction (J), and constant (C) regions in the polypeptides, which are generated with rearrangements of the gene clusters in human chromosome 14, in the proximity of the immunoglobulin heavy chain genes (IgH). These recombinations take place in the switching regions and the TCR genes also have the same hepta- and nanomeric sequences as the Ig genes. In the mouse, TCRA (α) genes are in mouse chromosome 14 whereas the Ig heavy chains of the mouse are in chromosome 12. The TCR δ chain locus is situated within the human α gene between the V_α and J_α regions. When the δ gene is excised, an excision circle is generated which includes also the excision signal joints (TREC). The human β chain of TCR is encoded in chromosome 7q22-7qter. (In mouse, its homolog is in chromosome 6). The expression of the β genes also requires rearrangement of the VDJ genes next to the C genes. The $\gamma 1$ and $\gamma 2$ chain genes are located in the human chromosome 7p15-p14 area, whereas their homologs are in mouse chromosome 6. The early lymphocytes carry TCR built of γ and δ polypeptides, whereas in the later, about 95% of the TCRs are built of α and β chains. The size of the $\alpha\beta$ TCR is about 80-kDa, built of four subunits. After the $\alpha\beta$ TCRs are formed, the $\gamma\delta$ TCRs are eliminated. The $\alpha\beta$ TCR is part of the protein complex CD3 γ , δ , ϵ , and ζ . These chains also contain 1 ITAM motif except ζ which has 3. Phosphorylation of the ITAM motif facilitates signal transduction from TCR. Subunit ζ determines largely the specificity by specific series of phosphorylations. In contrast to the $\alpha\beta$ antigen receptors, which recognize only peptides (fragments) bound to MHC molecules, the $\gamma\delta$ TCRs recognize the polypeptides without the

MHC molecules and also the MHC molecules without bound peptides. Also the $\gamma\delta$ TCRs may use non-peptide ligands such as phosphate-containing molecules. The TCR molecules are of a great variety, and are determined by rearrangements, just like in immunoglobulins. It appears that the TCR does not mutate somatically, in contrast to the Ig genes. The association of TCR either with Class I and Class II HLA gene products (MHC) augments the specificity of the TCR. The Class I HLA antigens are associated with the cytotoxic (killer) cells, whereas the helper lymphocytes attach to the Class II antigens. In the function of the TCRs, an important role is played by the CD4 (in Class I) and CD8 (in Class II associations). Both types of TCRs also require the CD3 transmembrane proteins complex involved in signal transduction. The CD peptides also activate some protein tyrosine kinases, important elements of several signal transduction pathways. Many forms of cancer are associated with chromosome breakage in the regions where the TCR proteins are coded. The human TCR β locus, consisting of 685 kb, has been sequenced. This large family includes, besides the TCR elements, other genes too, such as a dopamine-hydroxylase-like gene and eight trypsinogen genes. The large locus involves, besides the 46 functional genes, 19 pseudogenes and 22 relics (genes with major lesions in one or more components). A portion of the locus is translocated from chromosome 7q22–7qter to 9. The V β segments include promoters, the first exon as a signal peptide, with RNA splicing signals, the second exon is the V element and DNA rearrangement signal sequence. In some V β families a conserved decamer interacts with binding proteins.

T

TCV: ►Turnip crinkle virus

TD₅₀ (toxic dose): A dose causing toxic (carcinogen) effects in 50% of the experimental organisms. Frequently identified as mmol/kg/day. ►CASE

TDF (testis determining factor): ►sex determination, ►SRY, ►H-Y antigen

TDM: Tissue-specific differentially methylated regions in the genome (Song F et al 2005 Proc Natl Acad Sci USA 102:3336). ►methylation of DNA

T-DNA (transferred DNA): The T-DNA of the Ti plasmid is bordered by 24–25 bp incomplete direct repeats: TGGCAGGATATATT \overline{C}_A X \overline{A}_G TTGTAAA for the left and

TGGCAGGATATATT \overline{C}_A X \overline{A}_G TTGTAAA for the right in the octopine plasmids of *Agrobacterium*. The border sequences of the nopaline plasmids are somewhat different. The left part of the sequences within the borders, T_L (14 kb) and right, T_R (7 kb) are distinguished. The left segment carries, among others, genes for plant oncogenicity (coding for the plant hormones indole acetic acid and the cytokinin, isopentenyl adenine) and either octopine or nopaline, the right segment contains genes for other opines and others with unknown functions. The integration of the T-DNA into plant chromosomes is mediated by the virulence genes (VirA/G) of the Ti plasmid and some chromosomal loci rather than by the T-DNA sequences. In the plant tissues, phenolic compounds such as acetosyringone, cell wall sugars, and pH5.5 favor the transfer of the T-DNA. The transferred DNA of about 20 kb encodes the enzymes for the synthesis of indoleacetic acid and for cytokinin, required for tumorous growth in the plant. In addition, opine genes, which provide carbon and nitrogen nutrition for the growing tumor are transferred. In monocots (maize), 2,4-dihydroxy-7-methoxy-2H-1,4-benzoxazin-3(4H)-one (DIMBOA) inhibits *vir* genes as well as growth. The related compound 2-hydroxyl-4,7-dimethoxy-benzoxazin-3-one inhibits *vir* genes but not the growth of the tumor. These compounds may be the reason why it is so difficult to transform maize by *Agrobacterium*. After transformation is completed in dicots, the no longer needed *vir* genes are shut down by indoleacetic acid (Piu P, Nester EW 2006 Proc Natl Acad Sci USA 103:4658).

The T-DNA can integrate into the chromosome of plants by a process of illegitimate recombination at practically random locations. The integration involves most likely only one of the strands, called T-strand. The Ku80 protein of the plants appears to be involved in the recombination between an intermediate double-stranded DNA and the plant DNA (Li J et al 2005 Proc Natl Acad Sci USA 102:19231). Because of the transfer feature, the T-DNA can be utilized as the most efficient plant transformation vector. The oncogenes or other sequences can be deleted and replaced by any desired DNA sequences (genes) and they are still inserted into the plant chromosome as long as the border sequences are retained. In *Agrobacterium*, besides the T-DNA, multi-subunit protein complexes are also transmitted to the eukaryotic cell. ►*Agrobacterium*, ►Ti plasmid, ►transformation plants, ►virulence genes of *Agrobacterium*, ►binary vectors, ►cointegrate vectors, ►overdrive, ►opines, ►Ku; Koncz C et al 1992 Methods in Arabidopsis Research. Telemicroscopy: In telemicroscopy, a microscope linked to a computer transmits JPEG compressed images through the Internet network to distant viewers.

Teleology: A dogma attributing a special vital force and ultimate purpose to natural processes beyond the material scientific evidence. (See Lennox J 1981 J Hist Philos 19:219).

Telethonin: A Z-disc protein in the sarcomeres. It mediates the assembly of titin molecules. ▶ [sarcomere](#); Faulkner G et al 2000 J Biol Chem 275:41234.

Teliospores: Fungal spores protected by a thick wall; these are either dikaryotic or diploid (see Fig. T23). ▶ [stem rust](#), ▶ [telium](#)

Figure T23. Teliospores

Telium: A fruiting structure (sorus) of fungi producing dikaryotic teliospores.

Telocentric Chromosome: A telocentric chromosome has terminal centromere (has one arm) (see Fig. T24). Telochromosomes can be used to determine which genes are located in that particular single chromosome arm if a telotrisomic female is used according to the scheme represented in Figure T25.

Figure T24. Telochromosome

The segregation of $B:b$ in both the $2n$ and $2n + \text{telo}$ progeny is expected to be 1:1 (testcross). Among the $2n$ offspring, none or very few are expected to be A by phenotype because the telocentric egg cannot remain functional because of dosage effect of the essential genes in the missing chromosome arm. The A phenotype is usually due to recombination between the telo and the biarmed chromosomes. The $2n + \text{telo}$ offspring should be all A by a because of the dominant phenotype and none a because the dominant A allele is in the trisomic arm (see Fig. T25).

Figure T25. Gene localization with the aid of telochromosome

In allopolyploids, telochromosomes can be used to assign genes to the telochromosome and to determine recombination frequency between genes and the centromere. ▶centromere mapping in higher eukaryotes, ▶misdivision of the centromere [see Fig. T26], ▶Robertsonian translocation, ▶tetrad analysis, photo is the courtesy of Dr. ER Sears.

Telomerase (TERT [telomere reverse transcriptase]):

The enzyme synthesizing telomeric DNA. This enzyme is different from other replicases inasmuch as a RNA template (TERC) that is a part of the telomerase (ribozyme) specifies the telomeric DNA. An RNA polymerase II enzyme transcribes this RNA and it has a 5'-2,2,7-trimethyl guanosine cap. It has a binding site for Sm proteins that are characteristics for snRNPs. TERT (telomere reverse transcriptase) is the enzyme synthesizing telomeric DNA. The transcription of the human TERT (*hTERT*) is activated by the joint action of Sp1 and cMyc. It seems that the occupancy of the E box by either Myc or Mad1 determines the acetylation/deacetylation of the chromatin in HeLa cells and thus the regulation of human hTERT. This enzyme is different from other replicases inasmuch as a RNA template (TERC) that is a part of the telomerase (ribozyme), which specifies the telomeric DNA. The RNA has A and C repeats and therefore T and G repeats characterize the shortening of the telomeres that leads to p53-dependent senescence of the cells in vivo and limits tumor progression (Feldser DM, Greider GW 2007 Cancer Cell 11:461). The human telomerase template has 11 nucleotides: 5'-CUAACCCUAAC and the telomere has (5'-TTAGGG-3')_n repeats. In *Oxytricha*, the telomere consists of 36 nucleotides of which 16 form a single strand of 3'-G₄T₄G₄T₄ overhang protruding from the double-stranded remainder. The telomere-end-binding protein (TEBP) binds to the 3'-G₄T₄ tract and protects it from degradation. During replication this TEBP is displaced for the replication to proceed. By rejoining the end it displaces the telomerase and thus regulates telomere length. In murine embryonic stem cells but not in other types of cells, sister chromatid exchange at the telomeres may contribute to shortening of telomeres (Wang Y et al 2005 Proc Natl Acad Sci USA 102:10256). In budding yeast, the *TLC1* gene is responsible for telomerase activity and gene *EST1* is also needed for the maintenance of the telomeres. The *TLC1* (telomerase component) gene is also required for the preservation of the RNA template and normal telomerase function. The telomeres are made mainly of double-stranded DNA repeats, however the far end has only single strand G repeats. When the telomerase stays at the end of the chromosomes (capped state) the cells—even when the telomeres are short—remain viable. When the telomeres become uncapped the

cells exit from cycling and senesce. An automated highthroughput quantitative telomere FISH platform allows the quantification of telomere length as well as percentage of short telomeres in large human sample sets. This technique provides the accuracy and sensitivity to uncover associations between telomere length and human disease (Canela A et al 2007 Proc Natl Acad Sci USA 104:5300). Stronger and positive correlation and association seems to occur between telomere length (TL) in the offspring and paternal TL ($r = 0.46$), than offspring and maternal TL ($r = 0.18$) (Njajou T et al 2007 Proc Natl Acad Sci USA 104:12135).

The replication of the telomere takes place near the end of the cell cycle. Telomerase elongates only the G-rich strand and the C-rich strand is filled in later. In budding yeast, p23 molecular chaperone Sba1p controls telomere length maintenance and that Sba1p can modulate telomerase DNA binding and extension activities in vitro (Toogun OE et al 2007 Proc Natl Acad Sci USA 104:5765). Protein RCF binds also to the telomeric DNA and it is required for the replication of the leading strand by pol δ . The Pif1 helicase inhibits yeast telomerase by removing it from the DNA and may suppress healing of double-strand breaks by telomerase (Boulé J-B et al 2005 Nature [Lond] 438:57). Yeast cells recognize telomere replication as double-strand breaks and recruit to the telomeres the MRX complex of Mre11, Rad 50, and Xrs proteins. At late S phase, Mec1 is recruited to the telomeres where it assembles the Cdc13 and Est telomerase regulators (Takata H et al 2005 Mol Cell 17:573). Telomere-binding proteins (TEBP) bind either to the single-strand terminal repeats (*Oxytricha* proteins) or to the double strand sequences (Rap1). The telomeres of the ciliate *Oxytricha fallax* terminate in duplex DNA loops. The TEBP heterodimer α subunit (M_r 56K) binds to the 3'-T₄G₄ single-stranded end whereas the β subunit (M_r 41 K) attaches to other proteins. The heterogeneous nuclear ribonucleoprotein A1 (hnRNP A1) is also required for the maintenance of the normal length of the telomeres. The E6 protein of the Human Papilloma Virus-16 (HPV16) activates telomerase but does not immortalize the cells, although it expands their life span. The newly replicated telomeres are processed to size by proteins. Telomerase activity in tumor tissues is high but it is low in somatic cells or in benign neoplasias (Artandi SE, De Pinho RA 2000 Curr Opin Genet Dev 10:39). Intact telomere length and telomerase activity are required for the maintenance of function of epidermal stem cells (Flores I et al 2005 Science 309:1253). Targeting the telomerase by antisense technologies may be an approach to anticancer therapy. The telomerase RNAs of *Tetrahymena*, *Euplotes*, and *Oxytricha* seem to be transcribed by

polymerase III and the human telomerase RNA may be the product of pol II because it is sensitive to α -amanitin. The telomere end of *Tetrahymena* where it was originally discovered is somewhat different. In the RNA template, 5'-CAACCC-3', and in the telomere 5'-GGGTG-3' repeats occur. The Cdc13 protein of yeast mediates the access of the telomerase to the telomere. In the catalytic subunit of a telomerase of yeast (*EST2*, *ever-shorter telomeres*), reverse transcriptase-like motifs were identified. The telomeres are usually shortened as nuclear division proceeds and aging has been attributed to reduced telomerase activity. Lack of telomerase does not prevent tumorigenesis, however telomerase-deficient mice are resistant to skin tumorigenesis. Maintenance of normal telomere function is critical for the prevention of carcinogenesis. Usually in normal cells telomerase activity is barely detectable but it is well-expressed in tumor cells. The catalytic subunits bear structural similarities to reverse transcriptases. In mammals reduction in telomerase activity is harmful to the reproductive and blood-generating systems. On introduction into mammalian cells, an active telomerase may substantially extend the life of the cell. Telomerase defects increase the susceptibility to damage by ionizing radiation. Nevertheless, sustained telomerase activity does not result in malignancy. The ubiquitous c-MYC protein normally activates telomerase. The promoter of the TERT catalytic subunit has several c-MYC binding sites. Sheep produced by nuclear transplantation displayed apparently shorter telomeres than normally generated animals yet in the small-scale experiments no premature aging was observed. Mutations in the telomerase genes may result in senescence and late-onset sterility. Further, when the telomeres are substantially lost the chromosomes may fuse end-to-end. One class of *Caenorhabditis* telomerase mutants (*mrt*, *mortal germline*) is pleiotropic because in addition to the symptoms displayed by the other mutants in yeast and mice, it involves chromosomal loss and sensitivity to DNA-damaging agents. Mutation *mrt-2* was identified to have a defect in checkpoint function that is apparently repaired when the telomerase is normal. Loss of the telomerase function leads to swift progressive deterioration in animals but *Arabidopsis* plants may survive up to ten generations without telomerase function. However, eventually due to chromosomal aberrations both vegetative and reproductive fatal damage ensues. The human TERT expression is necessary for repairing chromosome breaks (Masutomi K et al 2005 Proc Natl Acad Sci USA 102:8222). In the presence of manganese, both human and yeast TERT can switch to RNA- and template-independent mode of DNA synthesis and act as a terminal transferase (Lue NF et al 2005 Proc Natl Acad Sci

USA 102:9778). TERT induction can also cause the proliferation of hair follicles—without a need for TERC, the RNA component of telomerase—and as a result abnormal heavy hair growth is observed in mice (Sarin KY et al 2005 *Nature [Lond]* 436:1048). Damaged telomeres can be repaired even in the absence of telomerase by relying on a break-induced recombination process (BIR). The pathways and mechanisms of BIR have been reviewed (McEachern MJ, Haber JE 2006 *Annu Rev Biochem* 75:111). ▶telomeres, ▶ribozyme, ▶RAP, ▶tankyrase, ▶pol II, ▶pol III, ▶α-amanitin, ▶*Tetrahymena*, ▶aging, ▶p16^{INK}, ▶ribozyme, ▶tumorigenesis, ▶antisense technologies, ▶hTERT, ▶malignant growth, ▶MYC, ▶Mad2/Mad1, ▶E box, ▶RNP, ▶cap, ▶SP1, ▶Myc, ▶nuclear transplantation, ▶MRX, ▶Mre11, ▶RAD50, ▶Xrs, ▶Cdc13, ▶Est, ▶pseudoknot, ▶p23; Collins K 1999 *Annu Rev Biochem* 68:187; Herbert B-S et al 1999 *Proc Natl Acad Sci USA* 96:14276; Tzfati Y et al 2000 *Science* 288:863; Cooper JP 2000 *Curr Opin Genet Dev* 10:169; Betts DH et al 2001 *Proc Natl Acad Sci USA* 98:1077; Wenz C et al 2001 *EMBO J* 20:3526; Antal M et al 2002 *Nucleic Acids Res* 30:912; Arai K et al 2002 *J Biol Chem* 277:8538; Neidle S, Parkinson G 2002 *Nature Rev Drug Discovery* 1:383; structure and function: Autexier C, Lue NF 2006 *Annu Rev Biochem* 75:493; history of discovery of telomerase: de Lange T 2006 *Cell* 126:1017; telomere replication review: Verdun RE, Karlseder J 2007 *Nature [Lond]* 447:924.

Telomere Crisis: The demise of the telomerase reverse transcriptase and the loss of telomere replication. The chromosome becomes unstable. ▶telomerase; Chin K et al 2004 *Nature Genet* 36:984.

Telomere Position Effect: ▶telomeric silencing

Telomere Switching: In *Trypanosoma*, the variable surface antigens (VSG) are encoded at the telomeres and frequent recombination of the chromosome ends can generate new variations and may affect the expression of the VSG glycoproteins. ▶telomeres, ▶*Trypanosoma*; Rudenko G et al 1998 *Trends Microbiol* 6:113.

Telomere Terminal Transferase: The ribozyme involved in replication telomeric DNA. ▶telomerase

Telomeres: Special terminal structural elements of eukaryotic chromosomes rich in T and G bases.

Electronmicroscopic observations indicate that in mice and humans the end of the telomeres bend

backward and form a D loop/t-loop as the telomeric single-strands pair with the double-stranded telomeric DNA (Figure T28). T loops normally prevent (NHEJ) non-homologous end joining recombination and the loss of the T loops may cause loss of telomere integrity (Wang RC et al 2004 *Cell* 119:355). In human chromosomes and all vertebrates, *Trypanosomas*, and fungi the many times repeated telomeric box is CCTAA/TTAGGG (ca. 300 bp). The telomeric region is highly conserved among diverse eukaryotes; in some species, however variations exist. In *Drosophilas* (and other insects), the telomeres are unusual inasmuch as rather than having the common repeats, they have transposable elements, e.g., *HeT-A* and *TART* in *Drosophila* (Casacuberta E, Pardue M-L 2003 *Proc Natl Acad Sci USA* 100:3363). This transposable element may assist the replication of the telomeric DNA. In most organisms proximal to the telomere, middle-repetitive DNA is found (telomere-associated DNA, TA), which may display some similarity to the *Drosophila* transposable sequences (Levis RW et al 1993 *Cell* 75:1083). The subtelomeric regions are repetitive and yet highly variable. Ectopic recombination in this tract may lead to restoring defective ends but it may be the cause also of undesirable rearrangements (Heather C et al 2002 *Nature Rev Genet* 3:91; Linardopoulou EV et al 2005 *Nature [Lond]* 437:94). The length of the telomeric sequences may vary among the organisms but variations exist during the life of the cells, according to developmental stage. By aging the telomeres usually become shorter in cultured cells although in mice telomere length may not be correlated with lifespan (Hemann MT, Greider CW 2000 *Nucleic Acids Res* 28:4474). The *Rtel* helicase-like gene (chromosome 2q) controls telomere length in mice and it essential for survival beyond days 10–11.5 of gestation (Ding H et al 2004 *Cell* 117:873). In maize, telomere-mediated truncation of chromosome ends appeared (Yu W et al 2006 *Proc Natl Acad Sci USA* 103:17331).

Mutants of shorter telomeres may function reasonably well, although a transient pause may occur in the cell division. The length of the human telomeres may be different between homologous chromosomes (Londoño-Vallejo JA et al 2001 *Nucleic Acids Res* 29:3164). Telomere length in humans is apparently linked to the X chromosome and the transmission occurs from father to son or father to daughter but no correlation was found between mother and son or mother and daughter (Nordfjäll K et al 2005 *Proc Natl Acad Sci USA* 102:16374). Various techniques are available for measuring the length of the telomeres. (Baird DM et al 2003 *Nature Genet* 33:203).

The non-nucleosomal special chromatin, including the repeats of yeast, is called telosome, which

contains six core proteins: TRF1, TRF2, RAP1, TIN2, POT1, and TPP1 (O'Connor MS et al 2006 Proc Natl Acad Sci USA 103:11874). TPP1 (telomere binding human homolog of TEBP) and POT1 (protection of telomere) form a complex with telomeric DNA that increases the activity and processivity of the human telomerase core enzyme. POT1–TPP1 seems to switch from inhibiting telomerase access to the telomere, as a component of *shelterin*, to serving as a processivity factor for telomerase during telomere extension (Wang F et al 2007 Nature [Lond] 445:506). However, in mammals the large telomeric DNA is nucleosomal. The major structural protein associated with the yeast telomeres is Rap1. TPP1 and TIN2 (TRF-interacting factor) are critical for the assembly of the telomeric complex. The same protein may also be present at other locations of the chromosomes and acts either as a repressor or activator of transcription. Telomeres are required for the proper replication of the linear eukaryotic chromosomes. This is probably the reason why among the diverse types of chromosomal aberrations cytologists failed to find attachments of internal chromosomal pieces to the telomeres or telomere to telomere fusions although chromosomes with broken ends may fuse into dicentric chromosomes after replication. Shortened telomeres may fuse and involve elevated frequencies of different types of chromosomal aberrations (Mieczkowski PA et al 2003 Proc Natl Acad Sci USA 100:10854). Normally, the telomeric repeat binding factor, TRF2, or DNA-dependent protein kinase (DNA-PK) prevents telomeric fusions. In ciliates, a cap is built at the telomere by binding TEBP α and β to 16-nucleotide single-strand DNA overhang. In fission yeast, the Taz1 protein protects the telomeric ends of the chromosomes from fusion, which otherwise might be mediated by the Ku proteins recognizing double-strand breaks (ends) of the DNA. In *taz⁻* cells *rad22* may also promote telomere fusion (Godinho Ferreira M, Promisel Cooper J 2001 Molecular Cell 7:55). In the budding yeast, telomere capping is mediated by Cdc13 protein that recruits other proteins (Ten1/Stn1) to build a protective cap. DNA-dependent protein kinase may play a critical role in capping (Gilley D et al 2001 Proc Natl Acad Sci USA 98:15084). In *Drosophila*, the HP1 protein interacts with histone methyltransferases and histone H3 methylated lysine 9 and participates in telomere capping, elongation, and silencing (Perrini B et al 2004 Mol Cell 15:467). In fission yeast, Pli1p is a SUMO E3 ligase and mutants are impaired for global sumoylation, yet they are viable, but exhibit deregulated homologous recombination, marked defects in chromosome segregation, and centromeric silencing, as well as a consistent increase in

telomere length. Telomere lengthening induced by lack of sumoylation is not due to unscheduled telomere–telomere recombination. Instead, sumoylation increases telomerase activity, suggesting that this modification controls the activity of a positive or negative regulator of telomerase (Xhemalce B et al 2007 Proc Natl Acad Sci USA 104:893).

In mammals, the TRF2 protein has an end-protective role. It may also remodel the chromosome ends by forming the so-called *t loop*. The *t loop* of mammals is double-stranded DNA. In both fission yeast and mammals, the *POT1* (protection of telomere) wild type allele encodes a telomere-capping protein, which binds to the G-rich telomeric single-strand tail and also to the *t loop*. POT1 in humans has some role in elongating the telomeres and may disrupt the G-quadruplexes to allow proper elongation (Zaug AJ et al 2005 Proc Natl Acad Sci USA 102:10864). Mice have two POT proteins (POT1 and POT2) whereas humans have only one (Hockermeyer D et al 2006 Cell 126:63). In budding yeast, the evolutionarily conserved KEOPS complex, including Cdc13, protein kinase and peptidase, is a telomere regulator (Downey M et al 2006 Cell 124:1155). In *Drosophila*, a zinc-finger protein, a putative transcription factor, encoded by gene *Woc*, prevents telomeric fusion (Raffa GD et al 2005 Mol Cell 20:821). The mammalian single-strand DNA with 3'-end may encompass 300 nucleotides and is located where the loop folds onto the main double-strand DNA (Baumann P, Cech TR 2001 Science 292:1171).

The structure of the telomere may bear some similarity to the centromere and in some instances (e.g., rye) it may function as a neocentromere. It may be somewhat of a puzzle how the normally fragmented somatic chromosomes of *Ascaris* are still able to produce their telomeres and how the germline chromosomes control the apparently multiple intercalary telomeres. In the polyploid ciliate macronucleus, millions of centromeres may exist in some species. HIV-infected individuals appear to have shorter telomeres than healthy individuals of comparable age. Telomere loss or inactivation may play a role in senescence and telomerase activation may be a mechanism of cellular immortalization. The replication of the telomeric DNA is carried out by the ribozyme, telomerase. A specific telomere-binding human protein hTRF (60 kDa), recognizing the TTAGGG (and mammalian) sequences, has been isolated. TRF1 (8q13) is regulated by TIN2 (TRF1-interacting nuclear protein). The corresponding repeat in *Tetrahymena* is TTGGGG and in yeast, TG_{1–3}. One of its domains is similar to the Myb oncogene product. Telomeric sequences may be shortened in several types of cancer cells, although

in about 90% of the malignant cell types the activity of the telomerase enzyme is higher than in normal cells. The enzyme poly(ADP-ribose) polymerase (PARP) that recognizes DNA interruptions, adds ADP-ribose units to the DNA ends. Defects in the encoding gene (ADPRP) and the protein PARP results in chromosomal instability and shortening of the telomeres. In *Caenorhabditis*, all chromosomes are capped by the same 4–9 kb tandem repeats of TTAGGC, but the sequences next to it differ among the chromosomes. Double-strand break repair proteins mediate the capping of the chromosomes. Intact telomeres cannot fuse but a repair pathway may generate non-homologous end-joining (NHEJ). When, however NHEJ fuses two telomeres, unstable dicentric chromosomes are produced. Chromosomes lacking telomeres can perform most functions but lack stability and undergo fusion, degradation, and loss at a high rate and the chromatids may not be able to separate normally. If yeasts lose the *TRT-1* telomerase subunit gene, the cells may survive either by circularizing the chromosome or by restoring the function through recombination controlled by *RAD50* or *RAD51* genes. In the majority of tumors, the telomeres are not shortened during consecutive divisions, whereas normal somatic human cells may lose 100 bp by each cell division and that may lead to discontinuation of cell divisions and cellular aging. In ciliates, telomeres may arise de novo but in yeast this rarely occurs. In humans, telomerase may rarely replace lost telomeres. Genes that would be normally transcribed by either pol I, pol II, or pol III are frequently repressed at the telomeric location (see Figs. T27 and T28). ▶telomerase, ▶breakage-fusion-bridge cycle, ▶neocentromere, ▶chromosome diminution, ▶immortalization, ▶senescence, ▶Myb, ▶RAP, ▶telomeric probe, ▶HeT-A, ▶TART, ▶plasmid telomere, ▶pol, ▶Ku, ▶non-homologous end-joining [NHEJ], ▶tankyrase, ▶dyskeratosis, ▶aging, ▶Werner syndrome, ▶TRF, ▶UbcD1, ▶ALT, ▶G-quadruplex, ▶Cdc13; Griffith JD et al 1999 Cell 97:503; Pardue M-L, DeBaryshe PG 1999 Chromosoma 108:73; Varley H et al 2000 Am J Hum Genet 67:610; Knight SJL et al 2000 Am J Hum Genet 67:320; McEachern MJ et al 2000 Annu Rev Genet 34:331; Hodes R 2001 Proc Natl Acad Sci USA

Figure T28. D- or t-loop formation of mammalian telomeres

Telomeric Fusion: As per telomeric fusion, end-to-end fusion of chromosomes does not take place between intact, telomere-capped chromosomes. However, it may take place in double-strand repair deficient cells. ▶non-homologous end-joining

Telomeric Probe: Telomeric probes are fluorochrome-labeled DNA sequences, complementary to the telomeric repeats TTAGGG; they can be used for the cytological identification of short (cryptic) translocations. ▶chromosome painting, ▶telomere

Telomeric Silencing (telomeric position effect): As per telomeric silencing, telomeres frequently reduce transcription of associated genes. This effect is similar to the silencing or position effect exercised by heterochromatin, although it may occur in this region even in the absence of heterochromatin. It may be due to higher order chromatin arrangement. Rap1 (repressor and activator protein) recruits the Sir3 and Sir4 (silent information regulators) and Rif1 (Rap1-interacting factor). Histones 3 and 4 and the Ku proteins are among the best known regulators. Mec1 (mitotic entry checkpoint) protein controls S-phase arrest of the cell cycle in reaction to DNA damage and regulates telomere length; some forms may also affect telomeric silencing. These genes/proteins are highly conserved but may have different names in the various organisms. In yeast, *DOT1* (disruptor of telomeric silencing) encodes a methyltransferase specific for histone 3 in the nucleosome globular domain and trimethylates lysine 79. The *Rmt1* methyltransferase dimethylates arginine at position 3 in histone-4 termini. ▶heterochromatin, ▶position effect, ▶telomeres, ▶RAP1A, ▶Ku, ▶silencers, ▶checkpoint, ▶MEC1; de Bruin D et al 2001 Nature 409:109; Lacoste N et al 2002 J Biol Chem 277:30421.

Telomutation: A (dominant) premutation occurring in and transmitted through both sexes but expressed

only in the offspring of the heterozygous female. ► [premutation](#), ► [delayed inheritance](#); Aleck KA, Hadro TA 1989 Am J Med Genet 33:155.

Telophase: The final major step of the nuclear divisions. The chromosomes have been pulled by the spindle fibers all the way to the poles. The microtubules attached to the kinetochores fade from view and the nuclear envelope reappears. The chromosomes relax and the nucleoli become visible again. ► [mitosis](#), ► [meiosis](#)

Telosome: A telocentric chromosome; the non-nucleosomal, six-protein chromatin complex at the end of the yeast, ciliate, and mammalian chromosomes is also called telosome or *shelterin*. ► [telomeres](#), ► [telochromosome](#); Liu D et al 2004 J Biol Chem 279:51338; de Lange T 2005 Genes Dev 19:2100.

Telotrisomic: A trisomic having two bi-armed and one telochromosome. ► [trisomy](#)

Telson: The most posterior part (opposite to the head) of the arthropod body. ► [Drosophila](#)

TEM (transmission electronmicroscopy): ► [electronmicroscopy](#)

TEM (triethylenemelamine): An alkylating clastogen. ► [alkylating agent](#), ► [alkylation](#), ► [clastogen](#)

TEM1: A GTPase. ► [GTPase](#)

TEMED: ► [acrylamide](#)

Temperate Phage: A temperate phage has both lysogenic and lytic life-styles. The temperate phages may be of different types: (i) those that insert their DNA into one or few preferred sites like λ phage, (ii) those that insert their DNA into the host bacterial chromosome with the aid of a transposase at different sites like Mu-1, (iii) those, e.g., P1, that do not insert their DNA into the host chromosome but are maintained as a plasmid and (iv) those, e.g., P4, which can be either plasmids or prophages. ► [bacteriophage](#), ► [lysogen](#), ► [lysogeny](#), ► [prophage](#), ► [plasmid](#), ► [lambda phage](#), ► [specialized transduction](#)

Temperature Conversion: $0.556^{\circ}\text{F} - 17.8 \rightarrow ^{\circ}\text{C}$, $1.8^{\circ}\text{C} + 32 \rightarrow ^{\circ}\text{F}$, $\text{K} - 273.15 \rightarrow ^{\circ}\text{C}$

Temperature-Sensitive Mutation (ts): The ts mutation causes such an alteration in the primary structure of the polypeptide chain that its conformation varies according to temperature, and it is functional at either high or low temperature but is non-functional at the other (non-permissive temperature). Temperature-sensitive conditional lethal mutants are very useful for various analyses because the biochemical/molecular basis of the genetic defect can be analyzed at the

permissive temperature range, within which, the cells or organisms grow (normally). ts condition is correlated with the buried hydrophobic residues in the protein. The majority of organisms (mesophiles) normally thrive best at temperatures $<40^{\circ}\text{C}$; hyperthermophiles may exist at temperatures around 100°C . Temperature variations are sensed by the transient receptor potential activation channels (Voets T et al 2004 Nature [Lond] 430:748). Inflammation and elevated temperature caused pain is controlled by the calcitonin gene-related neuropeptide and it is correlated with the differences in heat/pain response variations in mouse strains (Mogil JS et al 2005 Proc Natl Acad Sci USA 102:12938). ► [hyperthermia](#), ► [cold hypersensitivity](#), ► [pain-sensitivity](#), ► [trichothiodystrophy](#)

Template: A template determines the shape or structure of a molecule because it serves as a “mold” for it (in some way similar to the mold to cast iron). Old DNA strands serve as templates for the new, or one of the DNA strands may be a template for the mRNA and the other for another sense or nonsense RNA. Molecular biologists frequently call template (or antisense) the strand of the DNA that serves for the synthesis of mRNA by complementary base pairing. T7 RNA polymerase can bypass up to 24-nucleotide gaps in the template strand by copying a faithful sequence of the deletion using the non-template strand. ► [semiconservative replication](#), ► [replication fork](#), ► [sense strand](#), ► [coding strand](#)

Template Switch: As per the template switch, during replication the polymerase enzyme may jump to another DNA sequence and copy elements, which were not present in the original DNA tract. Such a switch may occur when plasmid DNA (T-DNA) is inserted into a chromosomal target site. As a consequence, deletions and rearrangements may follow. During primer extension, the strand displaced may reanneal onto the template and the extended strand may be partially dissociated. A single-stranded sequence, attached to the 5' end of the displaced strand and complementary to the dissociated segment of the extending strand, can thus serve as an alternative template ► [switch](#), ► [copy choice](#), ► [T-DNA](#), ► [primer extension](#); Negroni M, Buc H 2000 Proc Natl Acad Sci USA 97:6385.

Tenascin: A large glycoprotein complex with disulfide-linked peptide chains. It either promotes or interferes with cell adhesion, depending upon the type of cell and the different protein domains. It also controls cell migration, axon guidance embryogenesis, and oncogenic pathways. ► [cell migration](#), ► [cell adhesion](#); Hicke BJ et al 2001 J Biol Chem 276:48644; Daniels DA et al 2003 Proc Natl Acad Sci USA 100:15416.

Tendril: A plant organ that coils around objects and provides support (see Fig. T29). ►circumnutation

Figure T29. Tendril

Tensin: A cytoskeletal protein binding vinculin and actin; it contains an SH2 domain. ►actin, ►vinculin, ►multiple hamartomas, ►PTEN; Chen H et al 2002 Proc Natl Acad Sci USA 99:733.

Tension: The force(s) generated by pulling the mitotic/meiotic chromosomes to the opposite poles, opposed by the attachment between the homologs. ►spindle, ►kinetochore, ►pole

Teosinte: ►maize

TEP1 (TGFB β -regulated and epithelial cell-enriched phosphatase): A tumor suppressor function of PTEN. TEP1 is also an RNA-binding protein, which interacts with the mammalian and other telomerases. ►PTEN, ►vaults; Sharrard RM, Maitland NJ 2000 Biochim Biophys Acta 1494:282.

ter Sites: ►DNA replication prokaryotes

tera-: 10^{12}

Terahertz Radiation (T-rays): Electromagnetic radiation between microwaves and infrared. Semiconductor crystals of alternating layers of gallium arsenide and aluminum gallium arsenide emit light when electrons are boosted to higher level of energy by exposure to laser. Terahertz devices are expected to detect hidden objects of industrial and biological importance, such as anthrax pores within an envelope beyond what is detectable by other technologies. Apparently the T-rays are not harmful to living material. ►electromagnetic radiation

Teratocarcinoma: Malignant tumor containing cells of embryonal nature; common in testes. The teratocarcinoma cells may differentiate into various types of tissues in vitro and have been used for studies of differentiation. ►cancer, ►teratoma, ►stem cells;

Silver LM et al (Eds.) 1983 Teratocarcinoma Stem Cells, Cold Spring Harbor Laboratory Press, Cold Spring Harbor, New York.

Teratogen: Teratogens are agents causing malformation during differentiation and development.

Teratogenesis: Malformation during differentiation and development. The inducing agents may be genetic defects, physical factors and injuries, infections, drugs and chemicals. In frogs, limb developmental anomalies have been traced to trematode (*Planorbella campanulata* and *Ribeiroira* sp.) infection stimulated by agricultural pesticides. (See Kiesecker JM 2002 Proc Natl Acad Sci USA 99:9900).

Teratoma: A mixed tissue group with cells of different potentials for development. It may be formed in various early or late animal tissues and may eventually become a malignant tumor. Teratomas are most common in the germinal tissues. In plants amorph, undifferentiated tumor tissue may be interspersed with differentiated elements giving rise to either shoots or roots. Teratomas may be formed in the tumors induced by *Agrobacterium rhizogenes*. ►Agrobacterium

Tergite: The dorsal epidermis developed from histoblasts not from imaginal disks. ►histoblast

Terminal Deoxynucleotidyl Transferase (TdT): An enzyme that can elongate DNA strands—at the 3-OH end—with any base that is present in the reaction mixture. It is used in genetic vector construction to generate homopolymeric cohesive tails for the purpose of splicing a passenger DNA to a plasmid. The passenger and the plasmid are equipped with complementary bases, such as polyA and polyT, respectively, and can readily anneal and be ligated. Terminal nucleotidyl transferase is also expressed in the adult bone marrow and generates immunoglobulin diversity. The enzyme occurs primarily as a 58 kDa protein but much smaller molecules were also found. Its N-terminus is homologous to the C-terminus of the breast cancer gene, BRCA1. The N-terminus of TdT interacts with the heterodimeric Ku autoantigen, which is the DNA-binding component of a 460 kDa DNA-dependent protein kinase complex. This complex apparently plays a role (besides RAGs) in the generation of immunoglobulin diversity and DNA double-strand break repair. ►vectors, ►cloning vectors, ►immunoglobulins, ►T cell, ►breast cancer, ►Ku, ►RAG, ►immunoglobulins, ►double-strand break; Delarue M et al 2002 EMBO J 21:427.

Terminal Differentiation: Terminal differentiation is usually irreversible; in plants, however, under culture of high levels of phytohormones, dedifferentiation may be possible. ►dedifferentiation, ►differentiation

Terminal Nucleotidyl Transferase: The enzyme that can add homopolymeric ends to DNA. It is useful in generating cohesive termini (in genetic plasmid vectors), if one of the reaction mixtures contains adenylic acids and the other (e.g., passenger DNA), thymidylic acid (or G and C, respectively). ▶ [terminal deoxynucleotidyl transferase](#), ▶ [cloning vectors](#)

Terminal Protein (TP): Serine, threonine, or tyrosine residues of the terminal proteins provide OH groups for the initiation of replication, instead of 3' OH group of a nucleotide in a linear double-stranded viral DNA.

Terminal Redundancy: Repeated DNA sequences at the ends of phage DNA. (See permuted and non-permuted terminal redundancy.)

Terminalization of Chromosomes: During meiosis, the bivalents may display one or more chiasma(ta), which eventually (during anaphase) move toward the telomeric region in the process called terminalization (see Fig. T30). ▶ [meiosis](#)

Figure T30. Terminalization of chromosomes

Terminase: The terminase phage enzyme binds to specific nucleotide sequences and cuts in the vicinity of the binding at cohesive sites (*pac* or *cos*). ▶ [lambdaphage](#); de Beer T et al 2002 Mol Cell 9:981.

Termination Codons: ▶ [nonsense mutation](#), ▶ [genetic code](#), ▶ [terminator codons](#)

Termination Factors: The proteins that release the polypeptide chains from the ribosomes.

Termination of Replication in Bacteria: The termination of replication in bacteria is mediated by the homodimeric replication terminator protein (RTP). Two dimers bind to the two *Ter* inverted repeat sites in the DNA. The binding site has a strong core and an auxiliary site. First one dimer binds to the core and the binding of the second dimer follows this to the auxiliary site. When the replication fork encounters the RTP-*Ter* site, it is blocked, but not when it encounters it from the auxiliary site. The terminator prevents the unwinding of the DNA by the helicase. There are several *Ter* sites. (See Lemon K et al 2001 Proc Natl Acad Sci USA 98:212).

Terminator: The sequence at the end of a gene that signals for the termination of replication or transcription. The RNA polymerase recognizes this signal

directly or indirectly by various proteins. The intrinsic terminator of *E. coli* (*rho*) uses two sequence motifs for the release of RNA from the DNA template: (i) a stem-loop hairpin and (ii) a tract of 8–10 nucleotides immediately downstream at the end of the released RNA. Before termination, there is generally a pause, mediated by U-rich transcribing DNA segment. ▶ [transcription termination](#), ▶ [antitermination](#), ▶ [protein synthesis](#), ▶ [release factor](#), ▶ [rho factor](#), ▶ [pausing transcriptional](#), ▶ [RNA polymerase](#)

Terminator Codons: UAA, UAG, and UGA in RNA (same as nonsense codons).

Terminator Technology: Terminator technology uses three different transgenes in plants to control their ability to bear seed, to protect the interest of seed companies by preventing unauthorized use of their genetic stocks. One of the genes is a repressor of a recombinase, the other is a recombinase that is capable of deleting internal spacers, and the third is a toxin gene. The seed company can grow seed-bearing plants because the toxin gene is inactivated by a spacer sequence between the promoter and the structural toxin gene as long as the recombinase is suppressed. Treating the commercially sold seed by the antibiotic tetracycline, the synthesis of the suppressor is prevented, the recombinase then deletes the spacer, and the toxin gene becomes activated to cause seed failure. This trick of biotechnology may become a safeguard for the property of the company but may hurt the poor potential consumer who cannot afford buying the seeds annually. Similar, although simpler, technology has been practiced by the seed industry for decades in the commercially available double-flowered garden stocks. Although social activists condemn the terminator technology, its principles may offer promises for shutting off undesirable genes or activating useful ones, and serve beneficial roles in improving agricultural productivity ▶ [T-Gurt](#), ▶ [suppressor](#), ▶ [recombinase](#), ▶ [tetracycline](#), ▶ [promoter](#), ▶ [structural gene](#), ▶ [Mat-thiola](#); Kuvshinov VV et al 2001 Plant Sci 160:517.

Termisome: Nucleic acid terminal protein complexed with other proteins and DNA. ▶ [terminator](#), ▶ [protein synthesis](#)

Ternary: Ternary has two meanings; either that it is made up of three elements, or it is third in order.

Ternary Complex Factors: ▶ [TCF](#)

Terpenes: Hydrocarbons or derivatives (>30,000) with isoprene repeats; occur as animal pheromones and diverse types of plant fragrances. ▶ [pheromones](#), ▶ [fragrances](#), ▶ [prenylation](#), ▶ [Gossypium](#); Trapp SC, Croteau RB 2001 Genetics 158:811.

Terrestrial Radiation: Terrestrial radiation is emitted from the unstable isotopes in the soil, such as uranium-containing rocks. ▶cosmic radiation, ▶radiation hazard assessment, ▶radiation effects, ▶ionizing radiation, ▶isotopes

Terrific Broth (TB): Bacterial nutrient medium containing bacto-tryptone 12 g, bacto-yeast extract 24 g, glycerol 4 mL, H₂O 900 mL, and buffered by 100 mL phosphate buffer.

Tertiary Structure: The three-dimensional arrangement of the secondary structure of the polypeptide chain into layers, fibers, or globular shapea. It is also a third order of complexity, folding or coiling the secondary structure once more. ▶protein structure

Test Statistics: The specific procedure used to test a parameter or a null hypothesis.

Testa (seed coat): Maternal tissue in hybrids, therefore seed coat characters display delayed expression of recessive markers by one generation (e.g., to F₃) rather than in F₂.

Testcross: A cross between a heterozygote and a homozygote for the recessive genes concerned, e.g., (*AB/ab*) × (*ab/ab*); segregation is 1:1. ▶recombination frequency; *Arabidopsis* testcross photo (see Fig. T31); Rédei unpublished)

Figure T31. Segregation of a test cross progeny

T

Tester: A tester in a genetic cross is intended to reveal either the qualitative or quantitative gene content of the individual(s) tested. ▶testcross, ▶hybrid vigor, ▶combining ability

Testes (sing. testis): The male gonads of animals, producing the male gametes. ▶gonad, ▶gamete, ▶sex determination; Raymond CS et al 2000 Genes Dev 14:2587.

Testicles: Same as testes.

Testicular Feminization: Is a developmental anomaly, which occurs in humans and other mammals. The

chromosomally XY individuals display female phenotype including the formation of a blind vagina (no uterus), female breasts, and generally the absence of pubic hairs (see Fig. T32). Usually, the individuals affected by this recessive disorder (human chromosome Xq11.1-q12) appear very feminine but sterile. Generally, they develop abdominal or somewhat herniated small testes. About 1.5×10^{-5} of the chromosomally males have this disorder. The condition is the result of a complete or partial deficiency or instability of the androsterone receptor protein (917 amino acids). The function of this androgen receptor protein may be either totally missing or only partial (Reifenstein syndrome). This receptor appears to be highly conserved among mammals. The gene extends to about 90 kb DNA. The protein binds to DNA by two domains encoded by exons 2 and 3, five exons code for androgen binding, while exon 1 has a regulatory function. ▶chromosomal sex determination, ▶hermaphrodite, ▶hormone receptors, ▶pseudoherma-phroditism, ▶dihydrotestosterone, ▶Swyer syndrome, ▶sex reversal, ▶SF-1; Boehmer AL et al 2001 J Clin Endocrinol Metab 86:4151.

Figure T32. Testicular feminization. (Courtesy of Dr. McL. Morris)

Testicular Germ-Cell Tumor: The TGCT gene at Xq27 conveys susceptibility to this cancer affecting about 2×10^{-3} of men of Western European descent between ages 15–40.

Testin (TES, human chromosome 7q31-q31.2): A tumor suppressor in humans and mice. The protein contains three LIM motifs and is localized along actin fibers of the cytoskeleton. ►LIM domain; Drusco A et al 2005 Proc Natl Acad Sci USA 102:10947.

Testing, Genetic: ►genetic screening

Testosterone: The most important androsterone. Testosterone increases the risk of coronary heart disease and atherosclerosis. If testosterone is converted to estrogen by aromatase, the risk is reduced (see Fig. T33). ►animal hormones, ►hormonal effects on sex expression, ►progesterone

Figure T33. Testosterone

Testtube Baby: ►in vitro fertilization, ►intrauterine insemination, ►intra-fallopian transfer, ►ART

Testweight: The mass of 1,000 seeds or kernels randomly withdrawn from a sample. ►absolute weight

TET: Tetracycline antibiotic, inhibits protein synthesis, genetic (selectable) marker in the pBR plasmids. ►pBR322, ►tetracycline

TET (tubal embryo transfer): Essentially, the same as intrafallopian transfer of zygotes. ►intra-fallopian transfer, ►ART

Tet A: The tetracycline resistance protein that controls the efflux of the antibiotic from the cells. ►tetracycline, ►TetR

Tetanus: Tetanus toxin, ►tetany

Tetany: A highly stimulated condition of the nervous and muscular system caused by low levels of calcium due to various diseases and to infection by *Clostridium tetani*. Vaccines are available. The anaerobic, spore-forming soil bacterium with a genome size of 2,799,250 bp includes 2,368 open reading frames; it also has a low G + C content plasmid of 74,082 bp. ►biological weapons, ►*Clostridium perfringens*;

Brüggemann H et al 2003 Proc Natl Acad Sci USA 100:1316.

Tethering: Bringing together two distantly located nucleic acid sequences either by DNA looping, or catenanes or RNA lariats. ►introns, ►lariat RNA

Tet-OFF: ►tetracycline

Tet-ON: ►tetracycline, ►targeting genes

TetR: The tetracycline repressor (homodimer) regulates its own expression as well as that of the antiporter (TetA, which exports the drug from the cells) at the level of transcription and it is activated by $[Mg - Tc]^+$ complex. The tetracycline repressor binds to the dual operators of the TetR (repressor) and the TetA genes and blocks their transcription. Tetracycline alters the conformation of the repressor protein, which then is not capable of blocking transcription by the RNA polymerase at the operators even in some eukaryotes. This system is thus suitable for exogenous regulation—by tetracycline—of a gene promoter fused by genetic engineering to the TetR system. The failure of the system in eukaryotes is determined by the toxicity of tetracycline to a particular organism. ►tetracycline, ►antiport; Scholz O et al 2001 J Mol Biol 310:979.

Tetracycline (Tet): An antibiotic that prevents the binding of amino acid-charged tRNAs to the A site of the ribosomes (see Fig. T34). The tetracycline repressor gene (TetR) interferes with the expression of tetracycline resistance. Tetracycline in the medium prevents the binding of TetR to the DNA and relieves repression. Tetracycline is widely used as a tool in turning genes ON and OFF, respectively. When the TetR gene is fused to the activation domain of the Herpes simplex virus protein VP16, it becomes a very effective Tet-responsive transactivator (tTA) of other genes. In the absence of Tet or Tet analogs, the tTA binds the Tet operator (TetO) and initiates transcription. When Tet is present in the culture medium, the transactivator (TA) binds the antibiotic, the DNA binding is disrupted, and transcription is prevented. A mutant form of TetR protein binds to the TetO only in the presence of the antibiotic doxycycline, a Tet

Figure T34. Tetracycline

analog, and when fused to VP16 (rtTA) transcription is activated. Modification of the D ring yielded highly effective new enantiomorphs against some antibiotic resistant pathogens (Charest MG et al 2005 Science 308:395). ▶doxycycline, ▶pBR322, ▶ribosomes, ▶protein synthesis, ▶targeting genes, ▶tTA, ▶rtTA, ▶transactivator, ▶Gene-Switch, ▶antibiotic resistance; Chopra I, Roberts M 2001 Microbiol Mol Biol Revs 65:232; Stebbins MJ et al 2001 Proc Natl Acad Sci USA 98:10775.

Tetrad, Aberrant: The allelic proportions deviate from 2:2 because of polysomy, gene conversion, non-disjunction, suppression, etc. ▶polysomy, ▶gene conversion, ▶non-disjunction, ▶suppression

Tetrad Analysis: The meiotic products of ascomycetes (occasionally some other organisms) stay together as the four products of single meiosis, as a *tetrad*. In some organisms, tetrad formation is followed by a post-meiotic mitosis within the ascus, resulting in spore *octads*. If the four spores are situated in the same linear order as produced by the two divisions of meiosis it is an *ordered tetrad*.

In the ordered tetrad, considering two genes *A* and *B*, three arrangements of the spores (parental ditype [PD], tetratype [TT], non-parental ditype [NPD]) can be distinguished as seen in the Figure T35. The parental ditype (PD) indicates no crossing over; tetratype (TT) reveals one recombination between the two genes and the second division segregation of the B/b alleles reveals recombination between the B/b gene and the centromere (see Fig. T36).

The nonparental ditype (NPD) is an indication of double crossing over between the two gene loci. The PD, TT, and NPD may appear even if the genes are in separate chromosomes. An excess of PD over NPD is

an indication of linkage. If the deviation from the 1:1 ratio between PD and NPD is small, a *chi square test* may be used to test the probability of linkage by the formula: $\chi^2 = (PD - NPD)^2 / (PD + NPD)$.

By counting the number of tetrads of the above three types, *recombination frequency between the two loci* can be calculated as $\frac{[1/2]TT + \text{all NPD}}{\text{all tetrads}}$, and recombination frequency between the B/b gene and the centromere can be calculated as $\frac{TT[1/2]}{\text{all tetrads}}$. (Dr. Fred Sherman recommended to me to use for the gene-gene map distance the formula of Dr. David Perkins [Genetics 34:607], i.e. $100\{[0.5(TT) + 6NPD]/[PD + TT + NPD]\}$.)

The recombination frequencies (if they are under 0.15) multiplied by 100 provide the map distances in centiMorgans. If the recombination frequencies are larger, mapping functions should be used. From the genetic constitution of the tetrads, a great deal of information can be revealed about recombination. When the four meiotic products are not in the order brought about by meiosis, the tetrad is *unordered*. For the estimation of gene-centromere distances from unordered tetrad data, one must rely on three markers, from which no more than two are linked, and algebraic solutions are required (e.g., Whitehouse 1950 Nature 165:893, see unordered tetrads). Tetrad analysis is most commonly used in ascomycetes (*Neurospora*, *Aspergillus*, *Ascobolus*, *Saccharomyces*, etc.) (see Fig. T37) yet it can be applied to higher plants where the four products of male meiosis stick together (*Elodea*, *Salpiglossis*, orchids, *Arabidopsis* mutants). Using transgene constructs encoding pollen-expressed fluorescent proteins of three different colors in the *qrt1* mutant, which retains pollen in the tetrad stage, segregation of the fluorescent alleles in 92,489 pollen tetrads could be

Figure T35. Spore tetrads and octads without and with recombination

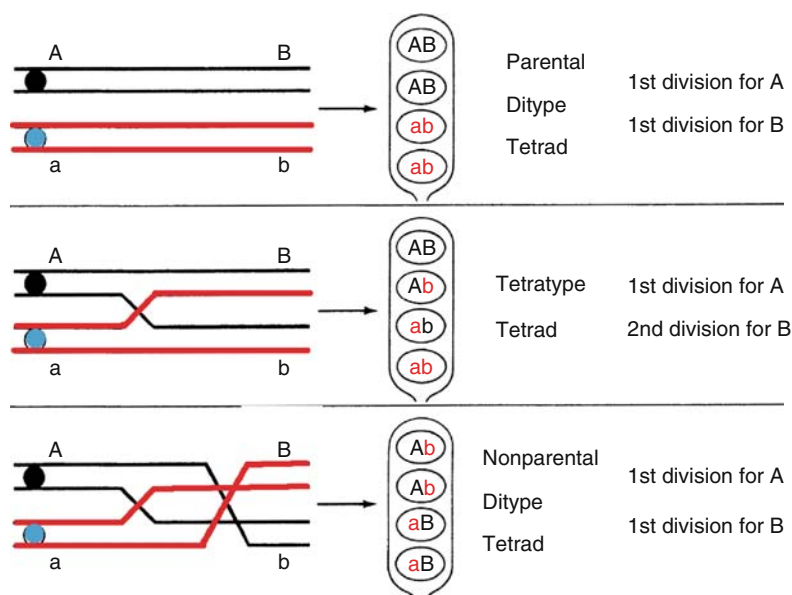

Figure T36. Transactions and results exemplified by two gene loci in an ordered tetrad. Gene A is so close to the centromere that practically no recombination occurs between them. (Diagram after Barratt RW et al 1954 Adv Genet 6:1)

Figure T37. *Neurospora* octads. (Courtesy of Dr. David Stadler)

observed (see Fig. T38). Correlation between developmental position and crossover frequency, temperature dependence for crossingover frequency, meiotic gene conversion, as well as interference were detectable (Francis KE et al 2007 Proc Natl Acad Sci USA 104:3913). In *Drosophila* with attached X-chromosomes half-tetrad analysis is feasible. Since several genomes of higher eukaryotes have been sequenced, molecular markers are available for tetrad analysis for the cases when the products of individual meioses can be identified. ▶unordered tetrads, ▶half-tetrad analysis, ▶meiosis, ▶mapping, ▶linkage, ▶mapping function, ▶four-point analysis of tetrads

Tetrahydrofolate (THF): The active (reduced) form of the vitamin folate, a carrier of one-carbon units in oxidation reactions, and a pteridine derivative. ▶hyper-homocysteinemia

Tetrahymena pyriformis: ($2n = 10$) is a ciliated protozoan with linear mtDNA. Its rRNA transcripts are self-spliced. ▶splicing, ▶mtDNA, ▶telomerase, ▶micronucleus, ▶macronucleus, ▶chromosome breakage programmed; Turkewitz AP et al 2002 Trends Genet 18:35; <http://www.lifesci.ucsb.edu/~genome/Tetrahymena/>; <http://www.ciliate.org/>.

Tetralogs: Paralogous gene groups originated by duplications (polyploidy), e.g., the families of multiple kinases or other genes. Some of these genes can be deleted without serious phenotypic consequence, yet their point mutations (dominant negative) may be quite deleterious, especially if they have multiple interactive domains and function in protein complexes. Some of the evolutionarily redundant genes can further evolve by selectable mutations. ▶polyploidy, ▶paralogous loci, ▶point mutation, ▶dominant negative, ▶duplication, ▶co-ortholog, ▶semi-ortholog; Spring J 1957 FEBS Lett 200:2.

Tetralogy of Fallot: ▶Fallot's tetralogy

TetraLoop: In structured RNAs, duplex runs are connected by loops of 5'GNRA (or UNCG or CUYG) tetranucleotides (N = any nucleotide, R = purine, Y = pyrimidine). They are involved in long-range molecular interactions, such as in hammerhead ribozymes and introns. ▶ribozymes, ▶introns,

Figure T38. Four-point cross with genes in both arms of the chromosomes. It is a five-point cross if we consider the centromere as a genetic marker. From the spore order we can determine even if the chromatids rotated 180° after the exchange. (After Emerson S 1963 p 167. In: *Methodology in Basic Genetics*. Burdette WJ (Ed.) Holden-Day, San Francisco)

Tetranucleotide Hypothesis: A historical assumption that nucleic acids are made of repeated units of equal numbers of the four bases (A, T/U, G and C), and because of this monotonous structure could not qualify for being the genetic material. It was probably first proposed around the turn of the twentieth century by the great German chemist, Albrecht Kossel, but became a rather widely accepted view during 1909 to 1940 through the brilliant yet erroneous work of Phoebus Levine. (See Levine PA 1909 *Biochem Zeit* 17:120; Levine PA 1917 *J Biol Chem* 31:591).

Tetraodon: ►[pufferfish](#)

Tetraparental Offspring: Tetraparental offspring results if in vivo fused blastulas of different matings are implanted together into the uterus. ►[allophenic](#), ►[multiparental hybrids](#), ►[chimera](#)

Tetraplegia (quadriplegia): Paralysis of the four limbs, caused by brain injury. Various mechanical devices have been designed to alleviate the incapacitation. Recent experiments inserting small neuromotor prostheses into the brain seem promising in

restoring control of movement (Hochberg LR et al 2006 *Nature [Lond]* 442:164). Brain-computer interfaces can provide means to operate computer cursors (Santhanam G et al 2006 *Nature* 442:195).

Tetraplex (quadruplex): Consecutive guanine sequences may take four-stranded parallel or antiparallel conformations in the DNA or RNA in several different configurations (see Fig. T39). The tetraplex structure may have biological significance for the telomeres, specific recombination of the immunoglobulin genes, dimerization of the HIV genome, etc. ►[telomere](#), ►[G-quadruplex](#), ►[immunoglobulins](#), ►[HIV](#); Simonsson T 2001 *Biol Chem* 382:621; Weisman-Shomer P et al 2002 *Nucleic Acids Res* 30:3672; Saccà B et al 2005 *Nucleic Acids Res* 33:1182; ►[tetrasomic](#)

Figure T39. Guanine (G) tetraplex

Tetraploid: Tetraploids have four sets of genomes (4x) per nucleus. Tetraploid plants have broader leaves and petals, and larger seeds (see Fig. T40). ▶[autopolyploidy](#), ▶[tetrasomic](#)

Tetraploid Embryo ComplEmentation: Embryonic stem cells have a unique ability to complete embryonic development after nuclear transplantation or after injection into tetraploid host blastocysts. Tetraploid mouse blastocysts cannot autonomously develop into embryos normally, but they can do so when complemented by diploid embryonic stem cells. The success is substantially better if the nuclei are not derived from inbred cells. Tetraploid embryo complementation assay has shown that mouse embryonic stem cells (ES) cells alone are capable of supporting embryonic development and adult life of mice. Newly established F1 hybrid ES cells allow the production of ES cell-derived animals at a high enough efficiency to directly make ES cell-based genetics feasible (George SHL et al 2007 Proc Natl Acad Sci USA 104:4455). ▶[stem cells](#), ▶[nuclear transplantation](#), ▶[embryo culture](#); Ewggan K et al 2001 Proc Natl Acad Sci USA 98:6209.

Tetrapod: The collective evolutionary designation of four-limbed vertebrate animals in contrast to lobe-finned fishes (sarcopterygians). ▶[missing link](#), Long JA et al 2006 Nature [Lond] 444:199.

Tetrasomic: In tetrasomics, one chromosome is present in four doses in the nuclei. Tetrasomy exists in tetraploids for all chromosomes and may not involve any serious anomaly although generally the fertility is reduced. Tetrasomy for individual chromosomes may have more serious consequences because of genic imbalance. Tetrasomy is usually not tolerated by animals. Tetrasomic mosaicism for human chromosome 12p leads to developmental anomalies, mental retardation, defects in the central nervous system and speech, etc. ▶[polyploidy](#), ▶[autopolyploid](#), ▶[trisomy](#), ▶[sex-chromosomal anomalies in humans](#), ▶[cat-eye syndrome](#)

Tetrasomic-Nullisomic Compensation: In allotetraploids, the homoeologous chromosomes may compensate for each other, and thus if two chromosomes are missing (nullisomy), and one type or their homoeologues is present in four copies (tetrasomy), the individuals may function rather well, depending on the particular chromosomes involved. When, however, in the presence of nullisomy a non-homoeologous chromosome is substituted, the condition is worsened. ▶[chromosome substitution](#), ▶[nullisomic compensation](#); Morris R, Sears ER 1967 p 19. In: Wheat and Wheat Improvement. Quisenberry KS, Reitz LP (Eds.) Am Soc Agron Madison, Wisconsin.

Tetraspanins: Cell membrane molecules functioning in cell adhesion, motility, proliferation, differentiation signal transduction, and fertilization. The TM4SF2 protein encoded at Xp11.4 and involved in determining a non-syndromic mental retardation also belongs to the tetraspanin family of proteins. ▶[CD9](#), ▶[CD63](#), ▶[CD82](#), ▶[mental retardation](#); Cannon KS, Cresswell P 2001 EMBO J 20:2443.

Tetratrico Sequences (TPR): Amphipathic α -helical amino acid tracts punctuated by proline-induced turns. CDC16, CDC23, and CDC27 of yeast and their homologs in other eukaryotes all contain tandem repeated ~ 34 -residues. Such motifs exist in more than 100 proteins and may control mitosis and RNA synthesis in the cells. ▶[APC](#), ▶[CDCs](#); Wendt KS et al 2001 Nature Struct Biol 8:784; Cortajarena AL, Regan L 2006 Protein Sci 15:1193.

Tetratype: The meiotic products concerned with two genes show four types of combinations (e.g., *AB Ab aB ab*). ▶[tetrad analysis](#)

Tetrazolium Blue: Tetrazolium blue detects oxidation-reduction enzyme activity and thus identifies living cells and cancerous metabolism.

Tetrodotoxin: ▶[toxins](#)

T-Even Phages: The designation has even numbers such as T2, T4, etc. ▶[bacteriophages](#)

Texas Red: A fluorochrome with excitation at 580 nm and emission peak at 615 nm. ▶[fluorochromes](#)

Text-Mining: The search for specific (overlooked) connections in the literature for the purpose of revealing specific trends/rules in multiple papers. ▶[literature mining](#)

Textpresso: The information retrieval and extraction system for *Caenorhabditis*. (See <http://www.textpresso.org/>).

TF: Transcription factors such as TF I, TF II, or TF III, involved in the control of transcription by pol I, pol II, or pol III, respectively; TFs assist transcription by

cooperation with other binding proteins. ▶transcription factors, ▶TFIIS, ▶open transcription complex

TF: ▶transferrin

Tfam: ▶mtFAM

TFD (transcription factor decoy): A double-stranded nucleotide sequence (e.g., $\begin{smallmatrix} \text{GGG} & \text{ACTTT} & \text{CC} \\ \text{CCC} & \text{TGAAAGG} \end{smallmatrix}$) that may sequester a transcription factor, e.g., NF-κB, within the cytoplasm by virtue of the attachment of the TF to a sequence homologous to its recognition site in the upstream region of the gene(s) in the nucleus. As a consequence, the nuclear gene may be (partially) silenced. Such an approach may be exploited for the control of oncogenes. ▶NF-κB, ▶antisense technologies; Mann MJ, Dzau VJ 2000 J Clin Invest 106:1071.

TFE: Helix-loop-helix leucine zipper transcription factor. ▶DNA binding protein domains

TFG: ▶transforming growth factor

TFII: ▶transcription factors, ▶TBP, ▶PIC

TFIIS: The eukaryotic transcript elongation stimulatory factor. It makes yeasts hypersensitive to 6-azauracil, which reduces the intracellular UTP and GTP pool. In *Drosophila*, the transcripts of two protein factors, N-TEF (negative transcript elongation) and P-TEF, regulate elongation. The positive effect is mediated by ATP-dependent phosphorylation of the RNA polymerase. ▶backtracking, ▶elongation factors, ▶transcription factors, ▶azauracil, ▶DSIF, ▶NELF, ▶TEF, ▶DRB, ▶PITSRE, ▶transcript elongation; Lindstrom DL, Hertzog GA 2001 Genetics 159:487; Ubukata T et al 2003 J Biol Chem 278:8580.

TFII: Synonymous with TBP.

TFM: ▶testicular feminization

TFO (triple-helix-forming oligonucleotide): TFO may be used to interfere with the activity of genes.

The effective TFO needs to recognize 10 to 17 bases in order to be gene specific. Some problems arise in vivo by the fact that genes in the chromosomes are organized as chromatin. TFO seems to mediate mutation, nucleotide excision repair, and transcription-coupled repair and consequently enhances mutation rate induced by UV-A in the presence of psoralen dye sensitization at 365 nm. Psoralen is a bifunctional photoreagent. TFO may also stimulate targeted gene conversion using nucleotide excision repair and may be antiviral. The triplex-directed, site-specific mutagenesis is much improved when cationic phosphoramidate linkages replace the phosphodiester backbone, particularly by employing *N,N*-diethyl-ethylenediamine to target short polypurine tracts (see Fig. T41). ▶antisense

RNA, ▶antisense DNA, ▶triple helix formation, ▶triplex, ▶inhibition of transcription, ▶peptide nucleic acid, ▶targeting genes, ▶directed mutation, ▶DNA repair, ▶ultraviolet light, ▶gene conversion, ▶psoralen, ▶pseudoknot; Vasquez KM et al 2000 Science 290:530; Vasquez KM et al 2001 J Biol Chem 276:38536; Besch R et al 2002 J Biol Chem 277:32473.

TGF: The transforming growth factors are cell proliferation inhibitors and their loss may be involved in cancerous growth. In humans, the TGFA gene is in chromosome 2p13, TGFB1 in 19q13.1-q13.3, TGFB2 in 1q41, and TGFB3 in 14q24. A member of the family, Vg1, a factor localized to the vegetal pole of the animal embryo, may be involved in the induction of mesoderm formation in the embryo. The TGF-β family cytokines activate the receptors of the heterodimeric serine-threonine kinases. TGF-β binds directly to TGF receptor II, a kinase. The bound TGF-β then, binds by the TGF receptor I and becomes phosphorylated (P) by it. Type I receptor contains a repeated GS (Gly.Ser) domain and a binding site for FKBP12. TGFR I then transmits the cytokine signal along the signaling cascade and the target genes may be turned on. In humans, about 30 members of the TGFβ protein family exist and various homologs—although in smaller numbers—occur in other species. TGFβ acts on cytotoxic T lymphocytes (CTL) and specifically inhibits perforin, granzyme A and B, Fas ligand, and interferon (Thomas DA, Massagué J 2005 Cancer Cell 8:369).

Ligand induced phosphorylation of receptor-activated Smads (R-Smads) is catalyzed by TGFβ type I receptor kinase. The PPM1A/PP2Cα phosphatase dephosphorylates and promotes nuclear export of Smad2/3. Ectopic expression of PPM1A abolishes TGFβ-induced antiproliferative and transcriptional responses but depletion of this phosphatase boosts

TGF β signaling in mammalian cells (Lin X et al 2006 Cell 125:915). The SMAD3 protein affecting the pathway outlined in the diagram is also a co-activator of the vitamin D receptor by forming a complex with the steroid receptor co-activator-1 protein (SRC-1) in the cell nucleus (see Fig. T42).

Figure T42. TGF signaling

TGF- α is an epidermal growth factor-like molecule. Mutations leading to chondrodysplasia involve members of the TGF family (CDMP1). Beta-glycan and endoglin cell surface proteins are also involved somehow with TGF. Endoglin and ALK1 (a type I receptor) mutations are found in hereditary hemorrhagic telangiectasia. TGF β receptor I mutations were found in different types of cancers and TGF β mutations may be responsible for heart disease, hypertension, osteoporosis, and fibrosis. TGF β mutations upregulate the transforming growth factor in the arterial wall in Loeys-Dietz syndrome and in aortic aneurism cause arterial tortuosity. The human genome includes 42 TGF β genes compared with nine in *Drosophila* and six in *Caenorhabditis*. ▶activin, ▶bone morphogenetic protein, ▶leukemia inhibitory factor, ▶ectoderm, ▶serine/threonine kinase, ▶signal transduction, ▶SMAD, ▶immunophilins, ▶SRC-1, ▶cytokines, ▶EGF, ▶MDM2, ▶FK506, ▶PP2A, ▶telangiectasia hereditary hemorrhagic, ▶Müllerian ducts, ▶Loey-Dietz syndrome; Massagué J 1998 Annu Rev Biochem 67:753; Massagué J, Chen Y-G 2000 Genes & Development 14:627; Massagué J et al 2000 Cell 103:295; Zwaagstra JC et al 2001 J Biol Chem 276:27237; Wakefield LM, Roberts AB 2002 Current Opin Genet Dev 12:22; Waite KA, Eng C 2003 Nature Rev Genet 4:763.

T-GURT (trait-specific genetic use restriction technology): T-GURT is applied to products of plant breeding with the aid of biotechnology and makes the plants express special traits such as salt or drought tolerance on condition that a special (chemical) treatment is applied. The plants will grow without the special treatment but do not express the agronomically advantageous special trait to the same extent. Such seed stocks protect the proprietary interests of the seed companies, which developed them. ▶terminator technology, ▶GMO, ▶RBF

T_H (or Th): T helper cell. They can be T_H1 type activating macrophages and T_H2 type, which activate primarily B cells. T-bet transcription factor regulates the activity of T_H1 cells. T_H1 cells produce IL-2, interferon- γ (IFN- γ), and tumor necrosis factor- β (TNF- β) and offer defense against intracellular pathogens by aiding cellular immunity. T_H2 cells make interleukin-4, -5, -6, -10, and -13 (IL-4, IL-5, IL-13) against extracellular pathogens and allergens, promote antibody formation, and have direct cytolytic activity. Interleukin-12 (IL-12) favors the development and maintenance of T_H1, whereas IL-4 promotes the differentiation of T_H2. IL-18 may both promote and hinder T_H2 activity by its effect on IL-13. T_H3 cells may express transforming growth factors. A new type of T helper cells T_H17 provides protection against extracellular bacteria and is involved in autoimmune diseases. T_H17 cells produce IL-17. Its development is linked to IL-23 and IL-12 and transforming growth factor TGF β , which is antagonized by interferon γ and IL-4 (Mangan PR et al 2006 Nature [Lond] 441:231). The differentiation factor for T_H17 is not IL-23 but IL-6 and TGF- β together. There is a different path for the development of the regulatory T_H17 cells that inhibit autoimmune tissues and T_H17 cells, which induce autoimmunity (Betteli E et al 2006 Nature [Lond] 441:235). ▶T cells, ▶B cell, ▶T-bet, ▶dendritic cell, ▶macrophage, ▶IL-4, ▶IL-5, ▶IL-6, ▶IL-10, ▶IL-12, ▶IL-13, ▶IFN- γ , ▶TNF, ▶TCCR; O'Garra A, Arai N 2000 Trends Cell Biol 10:542; Mullen AC et al 2001 Science 292:1907; Helmby H et al 2001 J Exp Med 194:355; Ho I-C, Glimcher LH 2002 Cell 109: S109; minireview: Reiner SL 2007 Cell 129:33.

Thalamus: A double-egg-shaped area deep within the basal part of the brain, involved in transmission of sensory impulses. ▶fatal familial insomnia, ▶brain human

Thalassemia: Hereditary defects of the regulation (or deletions) of hemoglobin genes, causing anemia. In the thalassemias, generally the relative amounts of the various globins is affected because of deletions of the hemoglobin genes. *Thalassemia major* is the most

severe form of the disease in patients homozygous for a defect in the two β -chains and who have an excessive amount of the F hemoglobin (HPFH: *hereditary persistence of fetal hemoglobin*). *Cooley's anemia* is also caused by β chain defects. *Thalassemia minor* is a relatively milder form with some hemoglobin A₂ present; usually, slight elevation of the F hemoglobin is characteristic for the heterozygotes. In the β -thalassemias, different sections of the β globin gene family from human chromosome 11p15.5 (5'- ϵ G γ $\psi\beta$ δ β - 3') are missing. The deletions may involve only 600 bp from the 3' end as in β^0 or about 50 kbp, eliminating most of the family beginning from the 5' end and retaining only the β gene at the 3' end in human chromosome 11p. In the β chain gene, about 100 point mutations and various deletions have been analyzed. In severe cases, the symptoms of the β thalassemias are anemia, susceptibility to infections, bone deformations, enlargement of the liver and spleen, iron deposits, delayed sexual development, etc. These may appear within a few months after birth. In the α -thalassemias (in human chromosome 16p13), various members of the α chain gene cluster (5'- ζ $\psi\zeta$ $\psi\alpha$ $\psi\alpha$ $\alpha 2$ $\alpha 1$ δ - 3') or even all four α chains are defective; the latter case results in the lethal hereditary disease, hydrops fetalis (Bart's hydrops), entailing accumulation of fluids in the body of the fetus and severe anemia, resulting in prenatal death. In α -thalassemia-1, both the $\alpha 1$ and the $\alpha 2$ genes are deleted, in thalassemia α -thal-2 only either the left (α *thal* 2L) or right end (α *thal* 2R) of the α -gene(s) is lost. The *Hb Lepore hemoglobin* is the consequence of unequal crossing over within the α gene cluster, resulting in N-terminal- $\delta\beta$ -C protein fusion. The N- $\beta\delta$ -C reciprocal protein fusion is called *Hb anti-Lepore* or *F thalassemia*. One of these types of hemoglobins was first reported in 1958 in the Lepore Italian family. Since then, a large number a Lepore type hemoglobins were discovered in various parts of the world and named Greece, Washington, Hollandia, etc., hemoglobin. The Xq13.1-q21.1 locus (ATRX) is a regulator of α -thalassemia and it usually involves mental retardation and a variety of developmental abnormalities. Thalassemias have much higher incidence worldwide in areas where malaria is a common disease. Homozygotes for thalassemias rarely contribute to the gene pool, thus the heterozygotes appear to have selective advantage in the maintenance of this condition. Some recent studies, however, indicate that α thalassemia homozygotes have a higher incidence of uncomplicated childhood thalassemia and splenomegaly (enlargement of the spleen an indication of infection by *Plasmodium*). This increase of susceptibility to the relatively benign *P. vivax* may provide some degree of immunization in the later stages of life against the more severe disease

caused by *P. falciparum* infection. This relatively high incidence of thalassemias in tropical and subtropical areas and the well-known molecular genetics mechanism makes this disease a candidate for somatic gene therapy by either bone marrow transplantation or transformation. The prevalence of thalassemias varies from about 10 to 5×10^{-4} . However, in some geographically isolated areas in the Mediterranean region, the frequency of the thalassemias may be much higher. Thalassemias are frequently associated with sickle cell anemias that are β globin defects and comorbidity aggravates the conditions (see Fig. T43). Prenatal diagnosis is possible by the use of protein or DNA technologies. Fetal mutation may be identified after PCR amplification of chorionic samples (9–12 weeks) or in directly withdrawn cells from the amniotic fluid after the third month of pregnancy. Hydrops can be identified by ultrasonic techniques during the second trimester. Transformation by a functional β -globin gene may ameliorate the condition in a mouse model. Erythroid specific expression of the transduced human α -globin gene and relatively high levels of expression of the human α -globin gene were observed in mice receiving the lentiviral vector by yolk sac vessel injection at midgestation. However, the expression decreased to low levels on long-term follow up (Han X-D et al 2007 Proc Natl Acad Sci USA 104:9007). ▶hemoglobin, ▶methemoglobin, ▶sickle cell anemia, ▶plasma proteins, ▶hemoglobin evolution, ▶unequal crossing over, ▶genetic screening, ▶PCR, ▶trimester, ▶*Plasmodium*, ▶antisense RNA, ▶Juberg-Marsidi syndrome, ▶ATRX, ▶hydrops fetalis; Weatherall DJ 2001 Nature Rev Genet 2:245; β -thalassemia review: Rund D, Rachmilewitz E 2005 New England J Med 353:1135.

Figure T43. Thalassemia blood smear. Irregular cells are characteristic

Thalidomide (*N*-phtaloyl

glutamide): A sedative and hypnotic agent of several trade names. It had been used experimentally also as an immunosuppressive and antiinflammatory drug. Its medical use as a tranquilizer during pregnancy caused one of the most tragic disasters in

medical history, resulting in severe malformations of primate embryos and newborns. It does not appear to be mutagenic and it is not teratogenic for other mammals. It is effective against multiple myeloma and possibly some other cancers. ▶[teratogen](#), ▶[phocomelia](#), ▶[amelia](#); Ashby J et al 1996 Mutation Res 396:45; Meierhofer C et al 2001 BioDrugs 15 (10):681; Richardson P et al 2002 Annu Rev Med 53:629.

Thallophyte: A plant, fungus, or algal body, a thallus. ▶[thallus](#)

Thallus: A relatively undifferentiated colony of plant cells without true roots, stem or leaves.

Thanatophoric Dysplasia: A dominant lethal human (4p16.3) dwarfism caused by deficiency of the fibroblast growth factor receptor 3, FGFR3. FGFR3 has constitutive tyrosine kinase activity, which activates the STAT1 transcription and nuclear translocation. This system also controls the p21^{WAF1/CIP1} protein involved in cell cycle suppression. Its prevalence is about 2×10^{-4} . ▶[dwarfism](#), ▶[fibroblast growth factor](#), ▶[STAT](#), ▶[p21](#), ▶[receptor tyrosine kinase](#), ▶[achondroplasia](#), ▶[Schneckenbecken dysplasia](#)

Thea (*Camellia sinensis*): 82 species, $2n = 2x = 30$. The epigallocatechin-3 component of green tea appears to be an angiogenesis inhibitor and thus can have anticancer effect. ▶[angiogenesis](#), ▶[angiostatin](#), ▶[endostatin](#), ▶[polyphenols](#); Kuroda Y, Hara Y 1999 Mutation Res 436:69.

Theileriosis: An African or East Cost Fever parasitic *Theileria* infection of the cattle's immune system, causing disease and death to the infected animals. In the T lymphocytes casein kinase II, a serine/threonine protein kinase is markedly higher. This protein is not identical with the common casein kinase found in lactating animals. *Theileria annulata* and *T. parva* are tick-borne protozoa ($n = 4$, genome size 8,351,610 and 8,308,027 bp, respectively). (See Pipano E, Shkap V 2000 Ann NY Acad Sci 916:484; Pain A et al 2005 Science 309:131; Gardner MJ et al 2005 Science 309:134).

Thelytoky: Parthenogenesis from eggs resulting in maternal females. ▶[ant](#), ▶[arrhenotoky](#), ▶[deuterotoky](#), ▶[sex determination](#), ▶[chromosomal sex determination](#); Normark BB 2003 Annu Rev Entomol 48:397.

Theobromine: The principal alkaloid in cacao bean, containing 1.5 to 3% of the base. It is also present in tea and cola nuts. The TDLo orally for humans is 125 mg/kg. It is a diuretic, smooth muscle relaxant, cardiac stimulant, and a vasodilator (expands vein passages). ▶[TDLo](#), ▶[caffeine](#)

Therapeutic Cloning: The generation of (human) stem cells that induces them to differentiate into a certain type of tissue which can be used to replace damaged tissues without the risk of rejection. The transfer stem cells are prepared by dislodging the nucleus of an oocyte and replacing it by the nucleus of an adult cell of the individual who is supposed to be treated by the stem cells. Such a modified oocyte (any type, possibly even from a different species) is then grown in culture until the blastocyst stage. The inner cell mass is then excised and cultivated in vitro until differentiated cells (either muscle, or neural, or hematopoietic cells) develop under the direction of the experimental conditions applied. Subsequently, the cells can be transplanted into the body of an individual. Nuclear transfer is possible between different species but the few experiments carried out so far could not maintain steady normal development. An alternative to the use of oocytes is to fuse an embryonic cytoplasm with an appropriate karyoplast. The ES cells do not develop into an embryo even it is transplanted into a uterus because the extra-embryonic membranes required would not be formed. If such a stem cell is introduced into a blastocyst, chimeric embryos (host + ES) may form in the mouse. These cells may form different types of tissues (pluripotent) but are apparently not totipotent. The therapeutic cloning is thus similar in some respects to reproductive cloning but current laws prohibit the latter in the majority of countries. Some of the cloned embryos suffered from (lethal) developmental anomalies. Although the majority of the implanted stem cells develop rather normally, some may become teratogenic and carcinogenic when transferred into mice. ▶[stem cell](#), ▶[nuclear transplantation](#), ▶[graft rejection](#), ▶[grafting in medicine](#), ▶[cytoplasm](#), ▶[karyoplast](#), ▶[blastocyst](#), ▶[totipotency](#), ▶[cloning animals and humans](#); Mitalipov SM 2000 Ann Med 32:462; Illmensee K 2002 Differentiation 69:167; Rideout WM III et al 2002 Cell 109:17.

Therapeutic Index: The therapeutic index reveals the dose of a drug with optimal, threshold, maximal tolerated or lethal, etc., effect in a particular organism or tissue. At high therapeutic index, a low dose gives the desirable effect without the possible toxic effects possible at higher doses.

Therapeutic Radiation: ▶[radiation hazard assessment](#)

Therapeutic Vaccine: vaccination may force down the level of an infective agent (e.g., HIV) and then eventually the natural immune system may overpower the infection. ▶[vaccines](#)

Thermal Asymmetric Interlaced-PCR: ▶[tail-PCR](#)

Thermal Cycler: An automatic, programmable incubator use for the polymerase chain reaction. ▶[PCR](#)

Thermal Neutrons: ►physical mutagens

Thermal Tolerance: Thermal tolerance is genetically determined and in plants may be affected by fatty acid biosynthesis and abscisic acid deficiency, etc. Heatshock proteins have also been credited with it. In *Tetrahymena thermophila*, a small cytoplasmic RNA (G8 RNA) is responsible specifically for thermotolerance independently from a heat shock response. ►temperature-sensitive mutation, ►heat-shock proteins, ►RNA G8, ►antifreeze protein

Thermatoga maritima: A thermophil (80° C optimum) bacterium; it has a completely sequenced circular DNA genome of 1,860,725 bp with 46% G + C content; 24% of its genes appear homologous to archaea bacteria. (Nelson KE et al 1999 Nature 399:323).

Thermodynamic Values: The thermodynamic values of chemicals are measured in calories; 1 calorie = 4.1840 absolute joule. ►joule

Thermodynamics, laws of: 1). When a mechanical work is transformed into heat, or the reverse, the amount of work is equivalent to the quantity of heat. 2). It is impossible to continuously transfer heat from a colder to a hotter body.

Thermoluminiscent Detectors: Thermoluminiscent detectors are used for personnel monitoring. In a small crystalline detector (lithium fluoride, lithium borate, calcium fluoride or calcium sulfate, and metal ion traces as activators), radiation is absorbed in the crystalline body and upon heating, is released in the form of light. The useful range is 0.003–10,000 rem. Radiophotoluminiscent (RPL) and thermally stimulated exoelectron emission (TSEE) detectors may be used instead of film badges in radiation areas. ►radiation measurements

Thermoplasma acidophilum: An archaea bacterium with a completely sequenced genome of $\sim 1.5 \times 10^6$ bp. Its temperature optimum is 59 °C, pH opt. 2. Its cells are without cell wall. ►Archaea; Ruepp A et al 2000 Nature [Lond] 407:508.

Thermosome: ►chaperonins

Thermotolerance: Some mutants of plants display increased growth relatively to the wild type at higher temperature. Some kinds of temperature-sensitivity are associated with differences in fatty acid biosynthesis. Thermosensation neurons in mammals are located in the keratinocytes of the skin (Moqrich A et al 2005 Science 307:1468). The tolerance of higher temperature in plants is correlated with reduced level in trienoic fatty acids. Trienoic acid synthesis is controlled by omega-3 fatty acid desaturase in the chloroplast membrane. If this desaturase is

silenced, photosynthesis is improved at higher temperature. ►cold-regulated genes, ►temperature-sensitive mutation, ►antifreeze protein, ►fatty acids; Mirkes PE 1997 Mutation Res 396:163.

THF: ►tetrahydrofolate

Theta Replication: θ is a stage of bidirectional form of replication in a circular DNA molecule (see Fig. T44). When the two replication forks reach about half way toward the termination sites, the molecule resembles the Greek letter θ . ►DNA replication, ► θ replication, ►bidirectional replication, ►replication, ►prokaryotes

Figure T44. Theta replication

"5,0,1,0,105pt,105pt,0,0>Thiamin (vitamin B₁): The absence of thiamin from the diet causes the disease beri-beri, alcoholic neuritis, and the Wernicke-Korsakoff syndrome. Its deficiency was the first auxotrophic mutation in *Neurospora*, and it is the most readily inducible auxotrophic mutation at several loci in lower and higher green plants, such as algae and *Arabidopsis* (see Fig. T45). The vitamin is made of two moieties: 2-methyl-4-amino-5-aminomethyl pyrimidine and 4-methyl-5- β -hydroxyethyl thiazole. The pyrimidine requirement of the thiamin mutants cannot be met by the precursors of nucleic acids. In *Arabidopsis*, more than 200 absolute auxotrophic mutations for thiamin have been isolated at five loci. This is remarkable because absolute auxotrophs in other metabolic pathways still need to be found in higher plants. ►thiamin pyrophosphate, ►Wernicke-Korsakoff syndrome, ►megaloblastic anemia, ►vitamins; Rédei GP, Koncz C 1992

Figure T45. Thiamin deficiency symptoms on *Arabidopsis* leaves, appearing after the vitamin supplementation ceased. A bleached band appears at about the upper third-fourth part of the leaf blade where the metabolism is most active (From Rédei, G.P., unpublished)

Methods in Arabidopsis research, pp 16–82. In: Koncz C et al (Eds.) World Scientific; Miranda-Ríos J et al 2001 Proc Natl Acad Sci USA 98:9736.

Thiamin Pyrophosphate: The coenzyme of vitamin B₁. It is an essential cofactor for pyruvate decarboxylase (alcoholic fermentation), pyruvate dehydrogenase (synthesis of acetyl Co-A), α -ketoglutarate dehydrogenase (citric acid cycle), transketolase (photosynthetic carbon fixation), and acatolactate synthetase (branched chain amino acid biosynthesis). ▶[thiamin](#); Frank RAW et al 2004 Science 306:872.

Thiazolidinediones: Antidiabetic (Type 2) drugs enhancing sensitivity to insulin. They are agonists and ligands to PPAR- γ receptors of adipocytes. They may have modest beneficial effects on the level of the desirable high-density lipoprotein (see Fig. T46). ▶[diabetes](#), ▶[PPAR](#), ▶[high-density lipoprotein](#), ▶[adipocytes](#), ▶[insulin](#); Yki-Järvinen H 2004 New England J Med 351:1106.

Figure T46. Thiazolidinedione

Thin-Layer Chromatography (TLC): The separation of (organic) mixtures within a very thin layer of cellulose or silica gel layer applied uniformly onto the surface of a glass plate or firm plastic sheet and used in a manner similar to paperchromatography. The material is applied at about 2 cm from the bottom and the plate is then dipped into an appropriate solvent (mixture). Generally, the substances are separated rapidly and with excellent resolution. Identification is made generally on the basis of natural color or with the aid of special color reagents. ▶[Rf](#)

Thioester: Acyl groups covalently linked to reactive thiol (see Fig. T47); they are high-energy acyl carriers in coenzyme A; also thioester may assist the formation of oligopeptide without any cooperation by ribosomes). There are suggestions that thioethers are the relics of prebiotic conditions when sulfurous (volcanic) environment existed on the Earth and might have played a role in the origin of living cells by being energy carriers. ▶[sulfhydryl](#), ▶[disulfide](#)

Figure T47. Thioester

Thioguanine (2-amino-1,7-dihydro-6H-purine-6-thione): An antineoplastic/neoplastic agent. Its delayed cytotoxicity is attributed to postreplicative mismatch repair. After incorporation into the DNA, it is methylated and pairs with either thymine or cytosine. The immuno-suppressant, azathioprine (6-[1-methyl-4-nitroimidazol-5-yl]-thiopurine), used in organ transplantation, can be converted to thioguanine and may be the cause of the increased incidence of cancer after transplantation. ▶[DNA repair](#), ▶[mismatch](#), ▶[base analogs](#), ▶[hydrogen pairing](#); Nelson JA et al 1975 Cancer Res 35:2872.

Thiol (SH⁻): Thiol compounds may reduce DNA breakage by scavenging radiation induced hydroxyl radicals and may repair the radicals chemically on the DNA by hydrogen atom transfer. Thiols have various regulatory roles in oxidative metabolism and nitrosative stress. ▶[sulfhydryl](#); Paget MSB, Buttner MJ 2003 Annu Rev Genet 37:91.

Thiopurine-S-Methyltransferase (TPMT): An enzyme, which can inactivate mercaptopurine and azathiopurine drugs, and is used for controlling cancerous growth. If the gene encoding TPMT is deficient for two of the same alleles (homozygous), excessive amounts of the drugs may accumulate and lead to potentially lethal hematopoietic toxicity unless much reduced (5–10% of the usual) doses are administered to the affected individuals. ▶[azathiopurine](#), ▶[mercaptopurine](#); Evans WE 2002 Pharmacogenetics 12:421.

Thioredoxins (TRX): ~12 kDa dithiol proteins that mediate the reduction of disulfide bonds in proteins. Also, light regulates photosynthesis through reduced thioredoxin, linked to the electron transfer chain by ferredoxin. Light also modulates translation in the chloroplast by redox potential. In insects it may substitute for glutathione reductase. Histone deacetylase inhibitors (suberoylanilide hydroxamic acid, and a benzamide) cause an accumulation of reactive oxygen species (ROS) and activation of caspases in cancer cells but not in normal cells. In normal cells, thioredoxin, a reducing agent, accumulates due to histone deacetylase inhibition but this does not happen in transformed cells. Thus, a selective apoptosis results, indicating therapeutic potentials (Ungerstedt JS et al 2005 Proc Natl Acad Sci USA 102:673). The thioredoxin domain of *E. coli* processivity factor represents a molecular switch, which regulates interaction of T7 DNA polymerase with other proteins of the replisome (Hamdan SM et al 2005 Proc Natl Acad Sci USA 102:5096). ▶[photosynthesis](#), ▶[photosystems](#), ▶[glutaredoxin](#), ▶[lysosomes](#), ▶[pullulanase](#), ▶[oxidative stress](#),

►processivity, ►replisome; Yano H et al 2001 Proc Natl Acad Sci USA 98:4794.

Thiostrepton ($C_{72}H_{85}N_{19}O_{18}S_5$): An antibiotic, binding to *E. coli* rRNA and 10 folds less effectively to yeast ribosomes. (See Porse DT et al 1998 J Mol Biol 276:391).

Thiotepa: An alkylating agent, formerly also used as an antineoplastic drug. It induces a very high frequency of sister-chromatid exchange. ►alkylating agent, ►sister chromatid exchange

Thiouracil: RNA base analog, carcinogen (?). Thiouracil—just as uracil—can base-pair with both adenine and guanine, while the analog-containing nucleic acids show enhanced resistance to nucleases and display increased thermostability. 2-Thiouridine regularly occurs at the first anticodon position (s^2 -U34) in place of uridine in the glutamate, lysine, and glutamine tRNAs. Thiouridine assures appropriate wobble for precise translation on the ribosome. The modified s^2 -U is also required for the proper assembly of the HIV-1 viral genome and for the viral reverse transcriptase primer. 4-Thiouridine (s^4 -U8) can be found at the junction of the acceptor stem and D stem of the tRNA (see Fig. T48).

Figure T48. Left: 2-thiouracil; right: 4-thiouracil

In *E. coli*, the MnmAS thiouridylase synthesizes s^2 -U with the aid of IscS desulphurase, which eliminates sulphur from L-cysteine. S is then transferred to MnmA via the Tus relay and it is incorporated in a precise manner into the correct tRNA site. The structural bases of the complex process was revealed by Numata T et al 2006 (Nature [Lond] 442:419). ►antisense technology, ►anticodon, ►tRNA, ►wobble, ►Tus, ►acquired immunodeficiency syndrome; Diop-Frimpong B et al 2005 Nucleic Acids Res 33:5297.

Third Messengers: Third messengers propagate signals of the second messenger and thus activate or deactivate a series of genes. ►second messenger

Thomsen Disease: ►myotonia

Thorax: The chest of mammals, the segment behind (posterior) the head in *Drosophila*.

Threading: A combinatorial alignment of amino acid sequences and DNA base sequences. On this basis a quantitative measure of protein-DNA binding can be derived statistically using, e.g., the Z score. The process permits a conclusion with regard to macromolecular structure. ►Z, ►binding protein; Papaleo E et al 2005 J Mol Model 21:1.

Three-Hybrid System: A construct that detects the role of RNA-protein interactions (see Fig. T49). ►two-hybrid system, ►one-hybrid binding assay, ►split-hybrid system; Koloteva-Levine N et al 2002 FEBS Lett 523:73.

Three M Syndrome (6p21.1): An intrauterine and postnatal growth retardation anomaly caused by impaired endovascular trophoblast invasion and reduced placental perfusion. It is caused by mutations in gene CUL7, which assembles the E3 ubiquitin

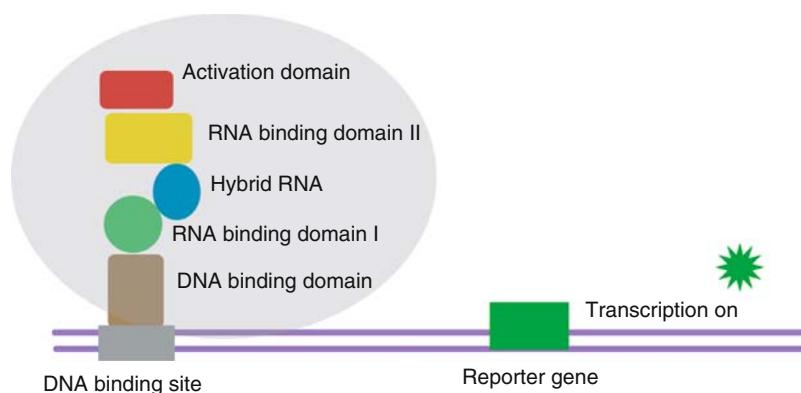

Figure T49. Three-hybrid system. The DNA-binding domain (e.g., LexA bacterial protein), the RNA-binding domain (e.g., MS2 phage coat protein), the top-binding proteins contain an RNA binding domain (e.g., IRP1[iron-response element]), and an activation domain (e.g., Gal4). The hybrid RNA (two MS2 phage RNAs) links the proteins together and in case of function the reporter gene (e.g., *LacZ*) is turned on. (Modified after Gupta DJS et al 1996 Proc Natl Acad Sci USA 93:8496)

ligase complex (Skp1, Fbx29 and ROC). ►ubiquitin; Huber C et al 2005 Nature Genet 37:1119.

Three-Point Testcross: The three-point testcross uses three genetic markers and thus permits the mapping of these genes in a linear order. ►mapping genetic, ►testcross

Three-Way Cross: A three-way cross is one in which a single-cross (the F₁ hybrid of two inbred lines) is crossed with another inbred. The purpose is to test the performance of the single-cross. ►combining ability

Threonine: This amino acid is derived from oxaloacetate via aspartate and immediately from:

Threonine dehydratase degrades threonine into α -ketobutyrate and NH_4^+ ; and then, after another five steps, isoleucine is produced from α -ketobutyrate. The first of these steps is mediated by threonine deaminase. ►isoleucine-valine biosynthetic steps, ►threoninemia

Threonyl tRNA Synthetase (TARS): TARS charges tRNA^{Thr} by threonine. It is encoded in human chromosome 5 in the vicinity of leucyl tRNA synthetase gene. ►aminoacyl-tRNA synthetase

Threose: A D-aldose sugar synthesized from D-glyceraldehyde (see Fig. T50).

Figure T50. Threose

Threose DNA: A synthetic molecule containing threose in place of deoxyribose (see Fig. T51).

Threose DNA and RNA are capable of base pairing despite the presence of the sugar analog.

Threshold Traits: Threshold traits are expressed conditionally when the liability reaches a certain level. These characters are frequently under polygenic control and yet they may fall into two recognizable classes—irrespective of whether they exhibit it or

Figure T51. Threose DNA

not—although with special techniques more classes may be revealed. Many pathological syndromes may fall into this category thereby making it very difficult to determine the genetic control mechanisms. ►syndrome, ►liability

Thrombasthenia: Autosomal dominant and autosomal recessive forms involving a platelet defect causing anemia and bleeding after injuries. The recessive form was assigned to human chromosome 17q21.32. ►platelet, ►anemia, ►thrombophilia

Thrombin (fibrinogenase): A serine protease enzyme that converts fibrinogen to fibrin and causes hemostasis (blood clotting). Thrombin also plays another role of an anticoagulant by the proteolytic activation of protein C in the presence of Ca^{2+} . These seemingly conflicting functions are modulated by allosteric alteration brought about by Na^+ and the thrombomodulin protein, changing the substrate-specificity of thrombin. The level of the activated protein C is further increased by a compound named LY254603. The protease-activated G protein-coupled receptor of thrombin (PAR1) is vitally important for embryonic development of mice. ►fibrin, ►fibrin-stabilizing factor deficiency, ►hemostasis, ►antihemophilic factors, ►plasmin, ►protein C, ►PAR, ►anticoagulation; Coughlin SR 2000 Nature [Lond] 407:258; Griffin CT et al 2001 Science 293:1666; carcinogenesis regulation by thrombin: Nierodzik ML, Karparkin S 2006 Cancer Cell 10:355.

Thrombocytes: The same as platelets.

Thrombocytopenia (TAR syndrome): An autosomal dominant bleeding disease (10p11.2-p12) caused by low platelet counts. Autosomal recessive (11q23.3-qter deletion and 21q22.1-q22.2) forms are associated with heart and kidney anomalies and absence of the

radius (the thumb side arm bone), phocomelia, etc. Another thrombocytopenia is linked in human chromosome Xp11. It is allelic to the Wiskott-Aldrich gene, WAS. Mutation in GATA1 may also cause the disease. The May-Hegglin anomaly, Fechtner syndrome, and the Sebastian syndrome involve macrothrombocytopenia (giant platelets) and leukocyte inclusions besides some specific symptoms. All three of these diseases show mutations in non-muscle myosin heavy chain 9. In some instances, the Epstein syndrome and the Alport syndrome display macrothrombocytopenia. ▶[Holt-Oram syndrome](#), ▶[Roberts syndrome](#), ▶[phocomelia](#), ▶[Wiskott-Aldrich syndrome](#), ▶[thrombopathic purpura](#), ▶[May-Hegglin anomaly](#), ▶[Alport disease](#), ▶[Kassabach-Merritt syndrome](#), ▶[GATA](#), ▶[dyserythropoietic anemia](#), ▶[platelets](#), ▶[giant platelet syndrome](#), ▶[radioulnar synostosis](#); Heath KE et al 2001 *Am J Hum Genet* 69:1033.

Thrombomodulin: ▶[thrombin](#), ▶[anticoagulation](#)

Thrombopathia (essential athrombia): A collection of blood clotting anomalies caused by problems in aggregation of the platelets. ▶[platelet abnormalities](#), ▶[hemophilias](#), ▶[hemostasis](#)

Thrombopathic/Thrombocytopenic Purpura (TTP, called also von Willebrand-Jürgen's syndrome, 9q34): TTP is caused by an autosomal recessive condition with symptoms resembling the bleeding and platelet abnormalities present in the Glanzmann's disease. The primary defect may involve the platelet membrane. Other symptoms may vary from case to case. Blood transfusion may shorten the time of bleeding. The basic defect is in the ADAMS13 zinc metalloproteinase genes. ▶[platelet abnormalities](#), ▶[hemophilias](#), ▶[hemostasis](#), ▶[thrombocytopenia](#), ▶[Glanzmann's disease](#); Levy GG et al 2001 *Nature [Lond]* 413:488.

Thrombophilia: A complex blood clotting disease that may occur as a consequence of mutation in any of the genes of antithrombin III, protein C, protein S, antihemophilic factor V, plasminogen, plasminogen activator inhibitor, fibrinogens, heparin cofactor, thrombomodulin, etc. Mutation at the 3'-untranslated region of the prothrombin gene may result in increased mRNA levels and protein synthesis due to this gain-of-function and to the disease. See separate entries, ▶[giant platelet syndrome](#), ▶[prothrombin deficiency](#); Gehring NH et al 2001 *Nature Genet* 28:389.

Thromboplastin: ▶[antihemophilic factors](#)

Thrombopoietin: Thrombopoietin regulates blood platelet formation and megakaryocytopoiesis. It is member of a cytokine receptor superfamily and it is similar to erythropoietin and granulocyte colony-stimulating factor receptors. In the brain, it is pro-apoptotic

(Ehrenreich H et al 2005 *Proc Natl Acad Sci USA* 102:862). ▶[megakaryocytes](#), ▶[platelet](#), ▶[erythropoietin](#), ▶[thrombocytopenia](#), ▶[G-CSF](#), ▶[apoptosis](#); Kato T et al 1998 *Stem Cells* 16:322; structure of receptor-binding domain: Feese MD et al 2004 *Proc Natl Acad Sci USA* 101:1816.

Thrombosis: A type of obstruction in blood flow caused by the aggregation of platelets, fibrin, and blood cells. Thrombosis may be caused by mutation in serpin. Antihemophilic factors V, VII, VIII, IX, XI, XII, the von Willebrand disease, tissue plasminogen activator, homocysteine and the activated protein C ratio display a genetic correlation with the incidence of thrombosis. ▶[antihemophilic factors](#), ▶[serpin](#), ▶[protein C](#), ▶[protein C deficiency](#), ▶[thrombocyclins](#), ▶[protein C](#), ▶[protein S](#), ▶[APC](#), ▶[cyclooxygenase](#), ▶[serpin](#), ▶[plasminogen activator](#); Souto JC et al 2000 *Am J Hum Genet* 67:1452.

Thrombospondin (THBS): Thrombospondin are glycoprotein inhibitors of angiogenesis. THBS1 (15q15) is a 180-K MW platelet membrane protein occurring on the endothelium, fibroblasts, and smooth muscles. THBS2 (6q27) binds thrombin, fibrinogen, heparin, plasminogen, etc. THBS2 functions as a tumor inhibitor by curtailing angiogenesis. Immature astrocytes express THBS and thereby promote synaptogenesis in the central nervous system (Christopherson KS et al 2005 *Cell* 120:421). ▶[angiogenesis](#), ▶[apoptosis](#), ▶[COMP](#); Hawighorst T et al 2001 *EMBO J* 20:2631; Rodríguez-Manzanique CC et al 2001 *Proc Natl Acad Sci USA* 98:12485; Adams JC 2001 *Annu Rev Cell Dev Biol* 17:25.

Thrombotic Disease: ▶[protein C deficiency](#)

Thromboxanes: Thromboxanes induce the aggregation of platelets and act as vasoconstrictors. They are antagonists of prostacyclin G₂ and may mediate intrauterine growth retardation. ▶[cyclooxygenase](#), ▶[prostaglandins](#)

Thumb: ▶[DNA polymerase](#)

Thy-1: A 19–25 kDa, single-chain glycoprotein expressed on mouse thymocytes but not on mature T cells of humans or rats.

Thylakoid: Thylakoids are flat, sac-like internal chloroplast membranes; when stacked they look like grana. Diacylglycerol galactolipids are common in these membranes but are absent from others. An estimated 80 proteins constitute the intra-thylakoid lumen. ▶[grana](#), ▶[chloroplast](#), ▶[girdle bands](#), (see Fig. T52); Dalbey RE, Kuhn A 2000 *Annu Rev Cell Dev Biol* 16:51; Schubert M et al 2002 *J Biol Chem* 277:8354; Kóta Z et al 2002 *Proc Natl Acad Sci USA* 99:12149.

Figure T52. Thylakoids

Thymidine: A nucleoside of thymine; thymine plus pentose (deoxyribose or ribose). (See formula of thymine at T).

Thymidine Kinase (thymidine phosphorylase): ▶TK

Thymidylate Synthetase: Thymidylate synthetase mediates the synthesis of thymidylic acid (dTMP) from deoxyuridine monophosphate (dUMP). Its gene is assigned to human chromosome 18p11.32. Its inhibition may lead to apoptosis. A number of nonsymbiotic archaea and bacteria lack this enzyme and use another protein, dependent on reduced flavin nucleotides rather than tetrahydrofolate as the source for reduction, as is the case in the majority of organisms. This is not a part of the salvage pathway. Thymidylate synthase may play an indirect role in carcinogenesis. ▶apoptosis, ▶salvage pathway, ▶synthase; Myllykallio H et al 2002 Science 297:105.

Thymidylic Acid (nucleotide of thymine): Thymine + pentose + phosphate.

Thymine: A pyrimidine base occurring almost exclusively in DNA. An exception is the T-arm of tRNA. ▶tRNA, ▶pyrimidines, formula at T.

Thymine Dimer: UV light-induced damage in DNA, covalently cross-linking adjacent thymine residues through their 5 and 6 C atoms. This cyclobutane structure interferes with the replication and other functions of the DNA. Cytidine and uridine can also form similar dimers. The dimers can be eliminated by enzymatic excision and replacement replication (excision or dark repair). Alternatively, the dimers can be split by DNA photolyase, an enzyme that is activated by visible light maximally at 380-nm wavelength (light repair). ▶DNA repair, ▶cyclobutane dimer, ▶pyrimidine-pyrimidinone photoproduct, ▶cys-syn dimer, ▶DNA polymerases; Medvedev D, Stuchebrukhov AA 2001 J Theor Biol 210:237.

Thymocytes: Thymocytes are precursors of T lymphocytes. Bone marrow stem cells migrate into the thymus and, in response to antigens, develop from

naïve $CD4^-CD8^-$ cells with the cooperation of the T cell receptors into double positive $CD4^+CD8^+$ cells that undergo clonal selection with the assistance of MHC molecules and eventually become specific T cells. ▶T cell, ▶T cell receptor, ▶MHC, ▶antigen presenting cells, ▶immune system, ▶memory immunological, ▶thymus

Thymoma: A cancer of the thymus. ▶AKT oncogene

Thymosins: A group of about 40 different proteins with an apparent immune-boosting ability. Thymosin $\alpha 1$ consists of 28 amino acids and thymosin $\beta 4$ contains 43. They may have therapeutic values. $\beta 4$ binds monomeric actin and prevents its polymerization into filaments. Its expression increases when cancer cells metastase. ▶actin, ▶metastasis; Hall NR, O'Grady MP 1989 Bioessays 11:141; Goldstein AL, Garaci E (Eds.) 2007 Thymosins in Health and Disease Ann NY Acad Sci 1112.

Thymus: A bilobal organ with three functionally important compartments—the subcapsular zone, the cortex and the medulla. The immature lymphoid cells coming from the bone marrow invade it. The subcapsular space contains most of the immature $CD4^-$ and $CD8^-$ lymphoid stem cells. When they enter the cortex they begin to express the CD molecules and they rearrange the T cell receptors and form the different TCR $\alpha\beta$ heterodimers. Defects in the genes of *Foxn1* and *Aire* of mouse cause immunodeficiency and autoimmunity, respectively. The epithelial cells in the cortex express MHC I and MHC II molecules. The fate of the T cell will be determined here in response to the MHC molecules carried by the antigen-presenting cells (thymic selection). The $CD4^+CD8^-$ cells with TCR recognizing the MHC II complex, or the $CD4^-CD8^+$ with TCR specific for MHC I will leave the thymus and populate the secondary lymphoid tissue. Those cells that do not acquire self-peptide-MHC specificity are eliminated. Those with strong avidity for self-peptide MHC die by apoptosis because they would be autoreactive (non-autoimmune). Aging (involution) reduces the thymic tissues and it was thought that this lead to a loss in their activity too. In the thymus, developing, autoreactive T cells undergo negative selection. Vascularized thymic lobe grafts from juvenile donors were capable of inducing tolerance in thymectomized juvenile hosts. Also, the aged, involuted thymus, transplanted as a vascularized graft into juvenile recipients, leads to rejuvenation of both thymic structure and function, suggesting that factors extrinsic to the thymus are capable of restoring juvenile thymic function to aged recipients. A rejuvenated aged thymus has the ability to induce transplant tolerance across class I MHC barriers

indicating that it may be possible to manipulate thymic function in adults to induce transplantation tolerance after the age of thymic involution (Nabori S et al 2006 Proc Natl Acad Sci USA 103:19081).

Newer evidence indicates the thymus can generate new peripheral T cells after antiviral treatment of HIV patients. In mice, a second lymphoid thymic structure may be present in the neck (cervical thymus) and its function is very similar to the thoracic thymus although its number of thymocytes is $\sim 1.6 \times 10^5$ whereas in the thoracic organ it is $\sim 10^8$ (Terszowski G et al 2006 Science 312:284). In the C57BL/6 strain, cervical thymus occurs in about 50% whereas in BALB/c mice its occurrence is in over 90%. ▶ **T cells**, ▶ **T cell receptor**, ▶ **TCR genes**, ▶ **MHC**, ▶ **autoimmune**, ▶ **spleen**, ▶ **HIV**, ▶ **nude mice**

Thyroglobulin: An iodine containing protein in the thyroid gland and has a hormone-like action upon the influence of the pituitary hormone. ▶ **animal hormones**

Thyroid Carcinoma: The transforming sequence was localized to human chromosome 10q11-q12, and a tumor suppressor gene in human chromosome 3p may be involved. Susceptibility loci to nonmedullary thyroid carcinoma have been revealed at 2q21, 19p13.2 and 1q21 (McKay JD et al 2001 Am J Hum Genet 69:440).

Thyroid Hormone Resistance: Dominant hyperthyroxinemia mutations (ERBA2) due to defects in the thyroid hormone receptor (3p24.3). (See Tsai MJ, O'Malley BW 1994 Annu Rev Biochem 63:451).

Thyroid Hormone Responsive Element: ▶ **TRE**, ▶ **hormones**, ▶ **hormone response elements**, ▶ **regulation of gene activity**, ▶ **goiter**

Thyroid hormone unresponsiveness: Autosomal recessive in humans. ▶ **hyperthyroidism**

Thyroid Peroxidase Deficiency (TPO): A group of recessive human chromosome 2p13 defects involving the incorporation of iodine into organic molecules.

Thyroid Stimulating Hormone (TSHB, 1p13): The β -chain and its deficiency leads to hypothyroidism, goiter, and cretinism. It also regulates both bone formation and bone resorption. ▶ **goiter**, ▶ **osteoporosis**

Thyroid Transcription Factor: The TTF-2 defect is responsible for thyroid agenesis and cleft palate in mice and the human homologue, FKHL1 (9q22), also controls the same functions and also choanal atresia (closure of the nasal passageways).

Thyronine (3p-[p(p-hydroxyphenoxy)-phenyl]-L-alanine): A component of the thyroglobulin of the

thyroid hormone. It generally occurs as 3,5,3'-triiodothyrosine. ▶ **VDR**

Thyrotropic: Affecting (targeting) the thyroid gland.

Thyrotropin: A thyrotropin deficiency is apparently due to a defect in the thyroid stimulating hormone β -chain defect at 1p13. Deficiency of the thyrotropin-releasing hormone (TRH, 3q13.3-q21) results in hypothyroidism and various malformations including defects in the development of the central nervous system. Hyperthyroidism may involve fast pulsation of the heart and goiter and adenoma. Hyperthyroidism may be transient during pregnancy. ▶ **goiter**, ▶ **adenoma**

Thyroxine: ▶ **goiter** (see Fig. T53)

Figure T53. Thyroxine

Thyroxine-Binding Globulin (TBG, Xq22.2): A deficiency of the thyroxine-binding globulin generally does not lead to disease although in Graves disease it may be more common. ▶ **goiter**, ▶ **Graves disease**

TI Antigens: TI antigens stimulate antibody production independently of T cells and in the absence of MHC II molecules. The TI type 2 (TI-2) has polysaccharide antigens, which are usually large molecules with repeating epitopes that activate the complement and are rather stable. The TI-1 type is mitogenic for mature and neonatal B cells. ▶ **antigen**, ▶ **antibody**, ▶ **T cell**, ▶ **MHC**; Vinuesa CG et al 2001 Eur J Immunol 31:1340.

Ti Plasmid: A large (about 200 kbp) tumor-inducing plasmid of *Agrobacterium tumefaciens*.

It is responsible for the crown gall disease of dicotyledonous plants. There are a few particularly important regions in this plasmid. The T-DNA of the octopine plasmid shown is divided into the left (T_L) and right (T_R) segments and is flanked by the two border sequences (B_L and B_R); in-between are several genes. The nopaline-type Ti plasmid (pTiC58) has only a single 20 kb T-DNA. The virulence gene cascade, and its function, is described under virulence genes of *Agrobacterium*. The origin of vegetative replication (*oriV*) is functioning during proliferation of the cells; the nearby Inc (incompatibility) site determines host-specificity. The *oriT* is the origin of replication operated on during conjugation. The latter is often called bom (base of mobilization) or CON

Figure T54. Major landmarks of the Ti octopine plasmid, pTiACH5. Arrowheads indicate the direction of transcription. T marks the T_L-T_R boundary

(conjugation) because the synthesis of the transferred DNA begins there. The actual transfer starts when the mob site encoded protein (Mob, synonym Tra) attaches to a specific nick site, a single-strand cut, and one of the strands (the T-strand) is transported to the recipient bacterial cell through the cooperation of some pore proteins. The oriT and Mob complex includes proteins TraI, TraJ, and TraH. TraJ attaches to a 19 bp sequence in the vicinity of the nick and binds also TraI, which is a topoisomerase. TraH promotes these bindings. The process is a rolling circle type replication and transfer. The integrity of virulence genes *virD* and *virB* are absolutely required for productive conjugation (see Fig. T54). ▶*Agrobacterium*, ▶T-DNA, ▶virulence genes of *Agrobacterium*, ▶transformation, ▶rolling circle, ▶conjugation; Hellens R et al 2000 Trends Plant Sci 5:446; Suzuki K et al 2000 Gene 242:331.

TIBO (O-TIBO and CI-TIBO): The non-nucleoside (benzothiadiazepin-derivatives) inhibitors of HIV-1 reverse transcriptase. ▶Nevirapine, ▶acquired immunodeficiency syndrome, ▶AZT

TIC (translation initiator-dependent cofactor): ▶TAF

TID50: A 56 kDa mitochondrial protein of *Drosophila*, encoded at 2–104 in the nucleus by the *l(2)Tid* tumor suppressor gene. It is homologous to the DnaJ chaperone. ▶chaperones, ▶DnaK, ▶tumor suppressor factors

Tie1, Tie2: Receptor tyrosine kinases, expressed during endothelial cell growth and differentiation of the blood vessels. ▶vascular endothelial growth factor, ▶Flk-1, ▶Flt-1, ▶tyrosine kinase, ▶transmembrane proteins, ▶signal transduction; Lin TN et al 2001 J Cereb Blood Flow Metab 21:690.

Tier: An ordered arrangement by increasing stringency of a series of tests, e.g., the first tier provides an overview of potential mutagens but subsequent tiers (using different techniques) may be necessary for clearance even when the first test might have been negative. Each tier may provide a different weight of evidence.

TIF1-α: Interacts with the steroid hormone receptor. ▶steroid hormones, ▶hormone receptors

TIF1-β: A transcription initiation factor of mouse binding to the core promoter of rRNA genes and controlling RNA polymerase I function. TIF1β is a component of the histone deacetylase complex. ▶transcription factors

TIF1-γ (TRIM33/RFG7/PTC7/Ectodermin): A Transcriptional Intermediary Factor, a protein that selectively binds receptor-activated Smad 2 and Smad 3. It mediates erythroid differentiation in response to TGFβ (He W et al 2006 Cell 125:929). ▶Smad, ▶TGF, ▶erythrocyte

Tight Junction (zonula occludens): A tight junction forms a seal between adjacent plasma membranes and provides a barrier to paracellular leakage of membrane lipids and proteins and thus guards cellular polarity (see Fig. T55). Tight junctions are apical domains of polarized epithelial and endothelial cells. The family of PDZ genes includes CLAUDIN 1, encoding a senescence-associated membrane protein; CLAUDIN 3, a *Clostridium perfringens* receptor [7q11]; CLAUDIN 4, a *C. p.* enterotoxin receptor; CLAUDIN 5, a velocardiofacial syndrome protein [22q11.2]; CLAUDIN 11, which mediates sperm and nerve functions [3q26.2-q26.3]; CLAUDIN 14, a deficiency responsible for deafness [21q22.3]; and CLAUDIN 16, which encodes paracellin, a paracellular

conductance protein associated with hypo-magnesia [3q27]; and others that are distributed over the genome. ZO-1 and ZO-2 proteins determine where the claudins are polymerized (Umeda K et al 2006 Cell 126:741). ▶deafness, ▶velocardio facial syndrome, ▶infertility, ▶PDZ; Tsukamoto T, Nigam SK 1999 Am J Physiol 276:F737; Tsukita A et al 2001 Nature Rev Mol Cell Biol 2:285; Gonzalez-Mariscal L et al 2003 Progr Biophys Mol Biol 81:1.

Figure T55. Tight junction of epithelial cells

Tiger (*Panthera tigris*): $2n = 38$. The tiger cat (*Leopardus tigrina*): $2n = 36$.

Tiglic Acid: A methyl-2-butenic acid. It is present with geranyl in the ornamental geranium and as an ester in the oil of chamomile (*Matricaria chamomilla*), a herbal medicine used as a tea or disinfectant.

Tiglicacidemia: A defect in the degradation of isoleucine to propionic acid leading to large amounts of tiglic acid accumulating in the urine.

TIGR: The Institute for Genomic Research in Rockville, MD, USA. ▶databases

TIL: ▶tumor infiltrating lymphocytes

Tiling: Generating a longer (minimally overlapping) DNA fragment map spanning the overall length of the genome or chromosome. By tiling, the transcribed sequences of the nucleus, chloroplast and mitochondria have been identified in *Arabidopsis* (Stolc V et al 2005 Proc Natl Acad Sci USA 102:4453). ▶physical map, ▶contig, ▶DNA crystals, ▶sequence-tagged connectors, ▶genome project, ▶scaffold in genome sequencing, ▶TUF, ▶noncoding RNA; Siegel AF et al 1999 Genome Res 9:297; Bertone P et al 2004 Science 306:2242; transcript maps: Cheng J et al 2005 Science 308:1149; Emanuelsson O et al 2007 Genome Res 17:886.

Tiling Microarrays: In microarray hybridization overlapping nucleotide sequences are used. ▶microarray hybridization

Tiling Path Array: A tiling path array includes a set of minimally overlapping clones.

Tiller: A lateral shoot of grasses arising at the base of the plant. (See Li X et al 2003 Nature [Lond] 422:618).

Tilling (targeting induced local lesions in genomes): Attempts to induce mutations by chemical mutagens (e.g., ethylmethane sulfonate) and use of denaturing high-performance liquid chromatography (DHPLC) to detect base alterations by heteroduplex analysis. By such a procedure 246 *waxy* alleles were identified in wheat. This holds promise of useful modifications without transgenic methods (Slade AJ et al 2004 Nature Biotechnol 23:75). ▶ethylmethanesulfonate, ▶HPLC, ▶*wx* gene, ▶heteroduplex; McCallum CM et al 2000 Nature Biotechnol 18:455; Till BJ et al 2003 Genome Res 13:524; <http://tilling.fhcrc.org:9366/>.

TIM (transfer inner membrane): A protein complex that regulates the import of proteins into mitochondria. ▶mitochondria, ▶TOM; Meinecke M et al 2006 Science 312:1523.

Time of Crossing Over: The time of crossing over appears to coincide with the meiotic prophase (late leptotene and early diplotene, probably at zygotene). Some experimental data indicate that treatments at S phase have an effect on the outcome. It is difficult to assess, however, whether these effects are direct or indirect. Meiosis is under the control of a long series of genes acting sequentially and cooperatively and any of these may affect crossing over. ▶crossing over, ▶recombination, ▶recombination mechanisms; Allers T, Lichten M 2001 Cell 106:45.

Time-Lapse Photography: Time-lapse photography records events continuously as they take place in time.

Timeless (Tim): A protein of *Drosophila* involved in the circadian clock. ▶circadian clock

Timothy Syndrome (long QT syndrome, 12p13.3): A calcium ion channel defect leading to Ca^{2+} accumulation in the cells. It causes a variety of abnormalities such as heart arrhythmia, webbed fingers and toes, immune deficiency, intermittent hypoglycemia, cognitive abnormalities, and autism (Splawski I et al 2004 Cell 119:19; Splawski I et al 2005 Proc Natl Acad Sci USA 102:8089). ▶QTL

TIMP (tissue inhibitor metalloproteinase): ▶metalloproteinases, ▶night blindness [Sorsby], Brew K et al 2000 Biochim Biophys Acta 477:267.

Tinkering in Evolution: The idea that evolution does not precede on the basis of purposeful plans; rather, it uses the means at hand at a particular stage. ▶evolution; Jacob F 2001 Ann NY Acad Sci 929:71.

TIP: Also known as tumor-inducing principle. ▶ *Agrobacterium*

TIP (tail-interacting protein): TIP47 (47 kDa) recognizes the cytoplasmic domains of mannose-6-phosphate and binds to Rab9. It facilitates the endosome to Golgi transport and recruits effector proteins for appropriate membrane targeting. ▶ *RAB*, ▶ *mannose-6-phosphate receptor*, ▶ *Golgi*, ▶ *endosome*; Carroll KS et al 2001 Science 292:1373.

TIP (T cell immunomodulatory protein): The T cell immunomodulatory protein causes secretion of IFN- γ , TNF- α and IL-10 in vitro; in vivo it protects against the host-versus-graft disease. ▶ *IFN*, ▶ *TNF*, ▶ *IL-10*, ▶ *host-versus-graft disease*; Fiscella M et al 2003 Nature Biotechnol 21:302.

TIP60 (HIV-1 Tat-interacting protein, 11q13): The 60 kDa regulator of HIV gene expression is a product of TIP60 (Kamine J et al 1996 Virology 216:357). The *Drosophila* TIP60 phosphorylates histone variant H2AX in case of DNA damage and remodels the chromatin by acetylation and replacement of H2A by an H2A variant (Kusch T et al 2004 Science 306:2084). ▶ *acquired immunodeficiency*, ▶ *prostate cancer*

Tipping Point: An epidemiological concept when treatment reaches a critical level resulting in a qualitative change, a turning of the tide of infections or inflammation (immune reaction) or the spread of the disease. It is a critical physiological stage in between health and disease.

TIR: Terminal inverted repeats as occurring in transposons ABCD—DCBA. It appears that hobo, Ac, TAM transposable elements have similar amino acid sequences although they occur in fungi, animals, and plants (Calvi BR et al 1991 Cell 66:465).

TIRAP (Mal): A PIP2 domain-containing adaptor controlling Toll-like receptor (TLR) signaling. It recruits MyD88 to TLR (Kagan JC, Medzhitov R 2006 Cell 125:943). Heterozygosity for leucine substitution at Ser180 in TIRAP attenuates Toll-like receptor signaling and increases resistance to infectious disease conveyed by *Plasmodium*, pneumococcal disease, bacteremia, and tuberculosis in diverse populations (Khor CC et al 2007 Nature Genet 39:523). ▶ *Toll*, ▶ *Toll-like*, ▶ *Plasmodium*, ▶ *Diplococcus/Pneumococcus*, ▶ *mycobacteria*, ▶ *PIP2*, ▶ *MyD88*

TIS1: ▶ *nur77* and ▶ *NGFI-B*

TIS-8: A mitogen-induced transcription factor. ▶ *NGFI-A*, ▶ *egr-1*

TIS11: A transcription factor, inducible by various hormones (similar to Nup475). ▶ *Nup475*

TIS11b: A murine homolog of cMG1. ▶ *cMG1*

TIS11d: A transcription factor with 94% identity to 367 amino acids in TIS11b. ▶ *TIS11b*

Tiselius Apparatus: An early model of electrophoretic separation equipment.

Tissue Culture: The in vitro culture of isolated cells of animals and plants. ▶ *cell culture*, ▶ *cell genetics*, ▶ *organ culture*, ▶ *cell fusion*, ▶ *somatic cell fusion*, ▶ *embryogenesis somatic*, ▶ *axenic*, ▶ *aseptic*

Tissue Engineering: The purposeful culture of stem cells for producing tissues and organs. For example, long-lasting blood vessels can be formed in mice by co-implantation of vascular endothelial cells and mesenchymal precursor cells. Submillimeter size collagen rods, seeded with endothelial cells, could be assembled into a man-made vascular system that permits percolation of blood through it. Such a construct is expected to be suitable for supplying blood into tissue without thrombosis, would delayed clotting time and inhibit loss of platelets (McGuigan AP, Sefton MV 2006 Proc Natl Acad Sci USA 103:11466).

Another approach is to deliver signaling molecules and cells on a three-dimensional scaffold that supports cell infiltration and tissue organization. Artery bypass experiments have shown that nanofibrous scaffolds allowed efficient infiltration of vascular cells and matrix remodeling. Acellular grafts without mesenchymal stem cells (MSCs) resulted in significant intimal thickening, whereas cellular grafts (with MSCs) had excellent long-term patency and exhibited well-organized layers of endothelial cells (ECs) and smooth muscle cells (SMCs), as in native arteries. Short-term experiments showed that nanofibrous scaffolds alone induced platelet adhesion and thrombus formation, which was suppressed by MSC seeding. Cell-seeded scaffolds provide proper environment for native tissue-like environment and can be well aerated at a small scale (Hashi CK et al 2007 Proc Natl Acad Sci USA 104:11915). Soft lithography permits the control of surface topography and spatial distribution of molecules on scaffold surfaces.

Replica molding of biocompatible polymers from patterned silicon wafers constructed from poly(dimethylsiloxane) (PDMS) or poly(DL-lactide coglycolide) (PLGA) or poly(glycerol sebacate) (PGS) are used. Hydrogels with gradients of signaling or adhesive molecules or various cross-linking densities can provide means for migration, adhesion, and

differentiation. Microfluidic technology can be employed on PLGA surfaces for the generation of two-dimensional patterns. A microtextured and nanotextured substrate may facilitate the generation of topographical features favoring cell adhesion, gene expression, and migration. For engineering bone tissues, porous ceramic or demineralized bone matrix support with bone marrow-derived mesenchymal cells and/or bone morphogenetic protein have been used with appropriate growth factors. Alternatively, in a space (called bioreactor) between the surface of a long bone and the membrane-rich periosteum (a connective tissue around the bone with the potentials of forming bone tissue) there is a niche for the injection of biocompatible calcium-alginate gel cross-linked in situ and it facilitates reconstitution of the functional living bone. The new microbioreactors provide a suitable niche, proper nutrients, and aeration for tissue fabrication. The engineered bone or liver tissue can then be transplanted to an area where bone tissue replacement is required. By inhibiting angiogenesis and promoting hypoxic conditions cartilage formation occurs (Stevens MM et al 2005 Proc Natl Acad Sci USA 102:11450). The availability of various types of stem cells and regulated culture conditions opens new approaches for the fabrication of special tissues. Experiments are in progress for the use of high throughput technology for tissue engineering. The goal is to replace defective human tissues with man-made tissues of high quality and without the danger of immune rejection. One product, Carticel, has been licensed for therapeutic use. Since 1997 more than 10,000 patients with injured knee cartilage have been treated with this autologous chondrocyte procedure (Parson A 2006 Cell 125:9). This is a very rapidly expanding field and by early 2006 more than 6,600 papers were published worldwide. By 2007, this number exceeded 8,500 although clinical applications are in infancy. ▶**stem cells**, ▶**progenitor**, ▶**anchorage dependence**, ▶**microfluidics**, ▶**lithography**, ▶**biotechnology**, ▶**wound healing**; Shin H et al 2003 Biomaterials 24:4353; Koike N et al 2004 Nature [Lond] 428:138; Nature Mater 3:249; Jakab K et al 2004 Proc Natl Acad Sci USA 101:2864; review: Khademhosseini A et al 2006 Proc Natl Acad Sci USA 103:2480; osteoblast formation: Datta N et al 2006 Proc Natl Acad Sci USA 103:2488; muscle degeneration after in vivo delivery of myoblasts on a scaffold: Hill E et al 2006 Proc Natl Acad Sci USA 103:2494; smooth muscle regeneration was greatly improved by ectopic expression of human telomerase reverse transcriptase transfection: Klinger RY et al 2006 Proc Natl Acad Sci USA 103:2500; review: Atala A 2006 Current Opin Pediatr 18(2):167; review: MacNeil S 2007 Nature [Lond] 445:874.

Tissue Factor (TF): A cell surface glycoprotein mediating blood clotting after injuries by its interaction with the clotting factor VIIa. It is also important for hemostasis, inflammation, angiogenesis, atherosclerosis, and cancer. Protein S has an inhibitory effect. ▶**antihemophilic factors**, ▶**blood clotting pathways**, ▶**Protein S**; Hackeng TM et al 2006 Proc Natl Acad Sci USA 103:3106.

Tissue Microarray (TMA): An adaptation of the microarray hybridization to tissue samples in order to reveal the cellular location of gene activity at the DNA, RNA or protein level. Cylindrical core specimens (biopsies) are acquired from formalin-fixed paraffin-embedded tissues and arrayed into high-density TMA blocks. Archival specimens are also suited for this analysis. Then, up to 300 5 µm sections are prepared for probing with DNA, RNA or protein using in situ hybridization (or FISH) or immunostaining. A single TMA allows the simultaneous study of the targets in thousands of specimens on microscopic slides. By TMA on a single slide the activity of one gene can be analyzed in 1000 tissue specimens. By microarray hybridization thousands of genes can be probed from a single tissue. TMA can be used to study cancerous tissue but it is not suitable for clinical diagnostics. This technique permitted the identification of some common transcriptional mechanisms in various types of cancer (Rhodes DR et al 2004 Proc Natl Acad Sci USA 101:9309) ▶**microarray hybridization**, ▶**FISH**, ▶**immunostaining**; Kallioniemi O-P et al 2001 Hum Mol Genet 10:657; ONCOMINE: <http://www.oncomine.org/meta>.

Figure T56. Tissue microarray

Tissue Plasminogen Activator (tissue plas): A tissue plasminogen activator cleaves plasminogen to plasmin and enhances fibrinolysis; it controls blood coagulation. ▶**blood clotting pathways**, ▶**PARs**

Tissue Remodeling: A coordinated series of events regulated by a balance between tissue proliferation and anti-proliferation factors such as cyclins, cyclin inhibitors and other metabolic regulators. Morphogenesis and various diseases involve alterations/anomalies in these processes. (See Nabel EG 2002 Nature Rev Drug Discovery 1:587).

Tissue-Specific Promoter: A tissue-specific promoter facilitates gene expression limited to certain tissues or organs. ▶**promoter**

Tissue-Specificity: The expression of a gene is limited to certain tissue(s). Tissue-specificity may be controlled at many levels (transcription initiation, differential recruitment of repressors or activators to the gene targets, promoter clearance, attenuator, transcription termination, etc.). The macrophage colony stimulating factor receptor gene is constitutively expressed in many cell types but only in the macrophages is the elongation of the transcripts permitted (see Fig. T57).

The evolutionarily determined size of a gene may have something to do with tissue-specificity. In the extremely fast dividing embryonic tissues the very large genes may not have enough time to be fully transcribed. The proportion of tissue-specific genes has been estimated by transformation of *Arabidopsis* with transcriptional and translational gene fusion vectors. Of the 200 transgenic plants about 10% displayed some degree of tissue-specific expression of the reporter gene (aph[3']). A large number of genes are expressed only in the central nervous system but repressed in other tissues. The REST/NRSF (repressor element silencing transcription factor/neuronal restricted silencing factor) along with the CoREST corepressor recruit histone deacetylase to chromosomal regions in the non-neuronal tissues to accomplish the task (Lunyak VV et al 2002 Science 298:1774). A computational model for the identification of cell-specific genes from the EST database is available (Nelander S et al 2003 Genome Res 13:1838). The identification of cis-regulatory elements and cognate transcription factors, expressed or inhibited in 45/56 different human and mouse tissues, permits a statistically significant predictions for tissue-specificity (Smith AD et al 2006 Proc Natl Acad Sci USA 103:6275). A global survey of specificity of 3,274 mouse proteins in six organs (brain, heart, kidney, liver, lung, and placenta) provides a searchable store for proteomics (see Fig. T58) (Kislinger T et al 2006 Cell 125:173; http://genome.dkfz-heidelberg.de/menu/tissue_db/faq.html). ▶transcription illegitimate, ▶housekeeping genes, ▶macrophage colony stimulating factor, ▶constitutive mutation, ▶aph, ▶subtractive cloning, ▶cascade

hybridization, ▶chromatin remodeling, ▶SATB1, ▶microarray hybridization, ▶isoenzymes, ▶EST, ▶organelle, Appendix II-10; Su AI et al 2002 Proc Natl Acad Sci USA 99:4465.

Tissue Typing: Determining the genetic constitution of a potential graft before transplantation. Blood typing is used. Even better, it can be done by DNA analysis (RFLP) or by polymerase chain reaction. ▶blood typing, ▶DNA fingerprinting, ▶polymerase chain reaction

Titer: The amount of a reagent in titration required for a certain reaction. The number of phage particles per volume determines phage titer by counting the pfu number on a bacterial lawn after a series of dilution. The vector titer is assessed by the expression of a reporter gene (e.g., GFP, galactosidase, luciferase) in the target cells on a plate. Alternatively, special RNA or DNA can be quantitated by PCR. ▶pfu, ▶reporter gene, ▶GFP, ▶galactosidase, ▶luciferase, ▶PCR

Titin (connectin): One of the largest protein molecules (3×10^6 M_r) along with nebulin; it forms a network of fibers around actin and myosin filaments in the skeletal muscles, and may also be involved in the condensation of the chromosomes. The human titin gene contains 178/234 exons. Titin keeps myosin within the sarcomeres by being anchored to the Z discs (membrane bands in the striated muscles) and assures that the stretched muscles spring back. Titin is made up mainly of repeated modules but at its C-end it also has threonine/serine kinase domain specifically phosphorylating myosin. Calmodulin is required for its activation. The titin kinase domain itself is activated by phosphorylation at a tyrosine residue. Mutation in titin at 2q31 may cause dilated cardiomyopathy and tibial muscular dystrophy. The titin N2B region is dispensable for cardiac development and systolic properties but is important to integrate trophic and elastic functions of the heart (Radke MH et al 2007 Proc Natl Acad Sci USA 104:3444). ▶nebulin, ▶glutenin, ▶sarcomere, ▶dystrophin, ▶calmodulin, ▶cardiomyopathy, ▶CaMK, ▶exon; Labeit S, Kolmerer B 1995

Figure T57. Tissue-specificity of expression (anthocyanin formation) of four different *R* alleles of maize in the aleurone, embryo, stalk, tassel and leaf tips

Figure T58. Transcriptome of 427 human and mouse gene pairs. Gene expression profile in 16 different types of tissues detected by Affymetrix GENECHIPS. Individual tissues express about 30 to 40% of the genes. Statistical analysis indicated that 78 to 82% of the genes were expressed differently in the mouse (M) and humans (H). The expression of the genes may be strictly tissue-specific. In this particular study, 85 human genes were expressed in the testis alone. (From Su AI et al 2002 Proc Nat Acad Sci USA 99:4465–4470; Copyright 2002 National Academy of Sciences, USA Courtesy of Dr. JB Hogenesch The Genomics Institute of the Novartis Research Foundation, San Diego, California)

Science 270:293; Machado C, Andrew DJ 2000 J Cell Biol 151:639; Gerull B et al 2002 Nature Genet 30:201; Hackman P et al 2002 Am J Hum Genet 71:492; Lange S et al 2005 Science 308:1599.

Titration: The addition of a measured amount of a solution of known concentration to a sample of another solution for the purpose of determining the concentration of the target solution on the basis of the appearance of a color or agglutination, etc. Also, by using this method, the number of cells or phage particles in a series of dilutions can be determined. ▶titer, ▶gene titration

TK: Thymidine kinase, which phosphorylates thymidine. Its gene in humans encodes the cytosolic enzyme that contains 7 exons in the short arm of human chromosome 17q25-q25.3; but the mitochondrial TK gene is in chromosome 22q13.32-qter. The latter enzyme defect may be responsible for myoneurogastrointestinal encephalopathy. The TK sequences are apparently highly conserved in different species. The herpes virus TK gene activates acyclovir and ganciclovir drugs and is used in gene therapy. ▶HAT medium, ▶gene therapy, ▶ganciclovir, ▶myoneurogastrointestinal encephalopathy

T_L: The left border of the T-DNA. ▶T-DNA, ▶Ti plasmid

TLC: ▶thin layer chromatography, ▶telomerase

TLE: ▶groucho, ▶Tup

TLF: ▶TBP

TLR: Toll-like receptor. ▶Toll

TLV (threshold limit value): The upper limit or time-weighted average concentration (TWA) of a substance that people can be exposed to without adverse consequences.

T_m: ▶melting temperature

TM1, TM2: Transmembrane amino acid domains of *E. coli* transducers, spanning the membrane layer inner space. TM1 is well conserved among the various transducers; TM2 is variable. ▶transducer proteins

TMF: TATA box modulatory factor. ▶TATA box, ▶promoter, ▶transcription

TMHMM2: A program for the detection of transmembrane topology helices.

TMP: Thymidine monophosphate (see Fig. T59). (See formula at right)

Figure T59. Thymidine monophosphate

TMRCA (time back to the most recent common ancestor): The concept for the study of the evolutionary descent of species or other taxonomic entities. It is estimated on the basis of the frequency of microsatellite variations associated with a particular mutation. If the mutation is recent the microsatellite variation linked to it is none and as time goes by the variation in microsatellites increases. The estimate may be biased by several factors, e.g., some variations may be lost by genetic drift, the generation time may be variable, etc.

tmRNA (10Sa RNA, SsrA): tmRNA basically is a tRNA and an mRNA hybrid molecule. It is used in bacteria to protect against the detrimental effects of mRNAs that lack stop codons and then stall translation. The SmpB (small protein B) protein binds to tmRNA and promotes its stable association with the 70S ribosome. The tmRNA is first charged with alanine and then it associates with EF-Tu. It binds to the A site of the ribosome and the alanine is incorporated into the growing peptide chain. Simultaneously, the mRNA-like domain of tmRNA substitutes for the defective mRNA on the ribosome. The tmRNA facilitates the inclusion of an additional 10 amino acids into the growing chain and then when the translation is stopped, the polypeptide is released. Proteins so formed are recognized by proteases because of the tmRNA tag and destroyed. This thus protects against defective proteins in the cell. This RNA is generated by RNase E cleavage. ▶aminoacylation, ▶regulation of gene activity, ▶eEF, ▶EF, ▶EF-Tu, ▶GTP, ▶proteasomes, ▶ribonuclease E, ▶protein repair, ▶ARAGORN, ▶ribosome recycling; Zwieb C et al 1999 Nucleic Acids Res 27:2063; Lee S et al 2001 RNA 7:999; Moore SD et al 2003 Science 300:72; structure and ribosome binding: Gutmann S et al 2003 Nature [Lond] 424:699; Asano K et al 2005 Nucleic Acids Res 33:5544; Moore SD, Sauer RT 2007 Annu Rev Biochem 76:101; <http://www.indiana.edu/~tmrna>; <http://www.ag.auburn.edu/mirror/tmRDB/>; <http://psyche.uthct.edu/dbs/tmRDB/tmRDB.html>.

TMS (tandem mass spectrometry): A method used to detect defects in fatty acid metabolism, organic acidemias and other human anomalies. ▶mass spectrum, ▶MALDI-TOF

TMV (tobacco mosaic virus): A single-stranded RNA virus of about 63,900 bases. Its cylindrical envelope contains 2,130 molecules of a 158-amino acid protein. Its rod-shape particles are about 3,000 Å long and 180 Å in diameter (see Fig. T60). The historical reconstitution experiments from coat protein and RNA demonstrated that RNA could be genetic material. Its mutagenesis by nitrous acid contributed substantially to the genetic confirmation of RNA codons. Its genome encodes four open reading frames. Foreign genes attached to the regulatory tract of the coat protein or to the coat protein itself can be expressed in tobacco plants. Thus, tobacco plants may be eventually used to manufacture proteins, e.g., α-glycosidase that is deficient in Fabry disease patients or the antigen of Hodgkin's lymphoma. ▶genetic code, ▶Fabry disease, ▶Hodgkin's disease, ▶plant vaccines; Goelet P et al 1982 Proc Natl Acad Sci USA 79:5818; Culver JN 2002 Annu Rev Phytopathol 40:287.

Figure T60. TMV

Tn3 Family of Transposons: Genetic elements that can move within a DNA molecule and from one DNA molecule to another and carry genes besides those required for transposition. The best-known representative is the Tn3 element carrying ampicillin resistance *Ap^r*. Tn3 is 4,957 bp long with 38 bp inverted terminal repeats and leaving behind—after moving at the transposition target site—5 bp direct duplication. Although the terminal repeats of the various Tn elements vary, some sequences are well conserved. The GGGG sequence is generally present outside the repeats and ACGPyTAAG is common inside of one or both terminal repeats. In the Tn3 group an internal ACGAAAA is common. Normally transposition requires the presence of both terminal repeats; the presence of only one of them may still allow a lower frequency transposition. The sites of integration may vary and yet AT-rich sequences are preferred and some homology between the terminal repeats and the insertional target may be needed. Some proteins of the host cell (IHF = integration host factor and FIS = factor for inversion stimulation) may

facilitate the expression of the transposase. Other members of the family are Tn1, Tn2, Tn401, Tn801, Tn802, Tn901, Tn902, Tn1701, Tn2601, Tn2602, and Tn2660. All are about 5 kb length with 39 bp terminal repeats and are found in various Gram-negative bacteria. Related to these is the $\gamma\delta$ (Tn1000) element in the F plasmid of 5.8 kb and with 36/37 bp terminal repeats and IS101 (insertion element 101), a cryptic element. Tn501 (8.2 kb) was the source of mercury resistance (*Hg^r*), Tn1721, Tn1771 (11.4 kb) for tetracycline resistance (*Tc^r*), Tn2603 (22 kb) for resistance to oxacillin (*Ox^r*), and hygromycin (*Hg^r*), streptomycin (*Sm^r*), and sulfonamide (*Su^r*). Tn21 (19.6 kb) carried resistance to *Su^r*, *Hg^r*, *Ap^r*, *Sm^r*, and *Su^r*. Tn4 (23.5 kb) was endowed with genes for *Ap^r*, *Sm^r*, and *Su^r*. Tn2501 (6.3 kb) was cryptic (i.e., expressed no genes besides the transposase). Tn551 and Tn917 (both 5.3 kb) from *Staphylococcus aureus* and *Streptococcus fecalis*, respectively, carried the erythromycin resistance (*Ery^r*) gene. The cryptic Tn4430 (4.1-kb) was isolated from *Bacillus thuringiensis*, R46 from enterobacteria, and pIP404 from *Clostridium perfringens* plasmids coded for the resolvase protein. The terminal repeats are generally within the range of 35–48 bp. The transposition is usually replicative and its frequency is about 10^{-5} to 10^{-7} per generation. The integration of the element requires the presence of a specific target site, called *res* site or IRS (internal resolution site), and genes *tpnA* (a transposase of about 110 MDa) and *tpnR*, encoding a resolvase protein (ca. 185 amino acids). The *res* site (about 120 bp) is where the resolvase binds and mediates site-specific recombination and protects the DNA against DNase I. Within the *res* site are located the promoters of *tpnR* and *tpnA* genes, functioning either in the same or in opposite direction, depending on the nature of the *Tn* element. The recombination between two DNA molecules requires the presence of at least two *res* sites in a negatively supercoiled DNA. The resolvase apparently has type I DNA topoisomerase function too. After synapses, mediated by resolvase and multiple *res* sites, strand exchange and integration may result. The recipient molecule thus acquires the donor transposon. The transposition event requires replication of the transposon DNA and then a fusion of the donor and the recipient replicons. This must be followed by a resolution of the cointegrate into a transposition product. ►transposable elements,

►gram-positive bacteria, ►transposon, ►cointegration, ►topoisomerase, ►antibiotics, ►resolvases; Sherratt D 1989, p 163. In: Mobile DNA. Berg DE, Howe MM (Eds.) Amer Soc Microbiol, Washington, DC.

Tn5: A bacterial transposon of 5.8 kb of the structure shown on Fig. T61.

The inverted termini represent the IS50 insertion element that includes the *tnp* (58 kDa protein) and *inh* genes (product 54 kDa). The left (L) and right (R) IS50 elements are almost identical except that the L sequences contain an ochre stop codon in the *tnp* gene, rendering it non-functional, save when the bacteria carry an ochre suppressor (see Fig. T61). At the I (inside ends) site binds the IHF (integration host factor) protein. O is the outside end of the IS sequence. Within the repeat beginning at nucleotide 8 is the bacterial DnaA protein-binding site TTATCA₈CA₈A. The DnaA product controls the initiation of DNA synthesis. Within the 2,750 bp central region are the genes for resistance to kanamycin (*kan*) and G418, bleomycin [phleomycin] (*ble*), and streptomycin (*str*) antibiotics; they are transcribed from the *p* promoter located within the IS L element at about 100 bp from the I end. These antibiotic resistance genes may not convey resistance in some cells, e.g., *str* may be cryptic in *E. coli*. The activation of this antibiotic resistance operon is contingent on the ochre mutation in the *tnp* gene. The inhibitor protein (product of *inh*) apparently interacts with the terminal repeats rather than with the transcription or translation of the *tnp* gene.

Tn5 can insert one copy at many potential target sites within a genome. The IS terminal repeats are capable of transposition themselves without the internal 2.8 kb element. In *direct transposition* the complete Tn5 will occur in the same sequence as shown in the diagram. In *inverse transposition*, mediated by the I ends, the 2.8 kb central element is left behind, away from the termini. Inverse transposition occurs 2–3 orders of magnitude less frequently than the direct one. In5 can form cointegrates with plasmids or bacteriophages and in these the IS elements and the entire Tn5 may occur and the orientation of the termini may be either direct or indirect as shown in the diagram. The transposon may be present as a monomer or as a dimer. Transposition may not require special homologous target sequences yet some targets represent “hot spots” (displaying

Figure T61. Structure of transposon Tn5

G•C or or C•G pairs next to the 9 bp target duplications) because they are preferred for insertion. The less frequently used targets generally show G•C and A•T pairs at the ends. Tn5 insertions, in general, are almost random and yet it appears that transcriptionally active promoters may present favorable targets. Insertion of the transposon into active genes usually results in inactivation because of the interruption of the coding sequences. Excision of the transposon may revert the gene to the original active state. This may occur at frequencies of 10^{-8} to 10^{-4} per cell divisions. The transposase gene alone does not mediate excision. It is independent from the bacterial *recA* gene but it depends on the structure of the inverted terminal repeats. Replicational errors involving slippage of pairing between the new and template DNA strands may occur. The presence of some sequences in the target may also promote Tn excision. The excision may also involve flanking DNA sequences and in this case the wild type function of the target gene is not restored. Several mutations in *E. coli* (*recB*, *recC*, *dam*, *mutH*, *mutS*, *mutD*, *ssb*) may promote excision, and mutation to *drp* reduces excision. Tn5, unlike Tn3, does not have a resolvase function. DNA gyrase, DNA polymerase I, DnaA protein, IHF and Lon (a protease cleaving effectively the Sula protein, a cell division inhibitor), may affect transposition. Transposition of Tn5 is substantially increased in *dam* mutant strains that are deficient in methylating GATC sequences. The *I* ends contain GATC sequence and can thus be affected by methylation. The *O* ends do not have a methylation substrate yet they are also affected by methylation in the *I* sequences (19 bp) (see Fig. T62). ▶transposon, ▶Tn3, ▶Tn7, ▶Tn10, ▶transposable elements bacteria, ▶transposable elements, ▶cut-and-paste, ▶resolvase; Berg DE 1989 Mobile DNA. Figure T63. Tn7. *dhfr* = dehydrofolate reductase gene with much reduced sensitivity to trimethoprim, an inhibitor of the enzyme involved in the biosynthesis of both purines and pyrimidines and thus nucleic acids. *aadA* = adenylyl transferase gene, encoding an enzyme, which inactivates aminoglycoside antibiotics, streptomycin and spectinomycin, and thus conveys resistance to the cells. The *tns* genes are responsible for transposition

Tn7: A 14 kb bacterial transposon of the following general structure. The Tn7 element has a high capacity to insert into the specific *att* Tn7 site of *E. coli* (25 kb counterclockwise from the origin of replication at map position 83). The target DNA required for Tn7 transposition is within the C-terminus of the glucosamine synthetase (*glmS*) gene in bacteria and it has similar specificity for the human homolog of *glmS*, GFPT-1 and GFPT-2, at chromosomal location 2p13 (Kuduvalli P et al 2005 Nucleic Acids Res 33:857). When this site is not available it may transpose—at about two orders of magnitude lower frequency—to a *pseudo-att* Tn7 or to some other unrelated sites (see Fig. T63). At the *att* Tn7 the right end is situated proximal to the bacterial *o* gene. Genes *tnsABC* mediate all transpositions but through different pathways; for transposition to *att* Tn7 and *pseudo-att* Tn7, the function of gene *D* is also required, whereas for transposition to all other sites the expression of the *ABC + E* genes are needed. (The name *tns* abbreviates transposon seven.) The insertion at *att* Tn7 is also in a consistent orientation and it is within an intergenic region and thus does not harm the host. Insertion of the Tn7 element protects the cell from an additional Tn7 insertion (immunity). Yet under some conditions the immunity may not work. Integration results in 5 bp target site duplication; these duplications are different at *att* Tn7 and other sites. Several bacterial species besides *E. coli* have specific *att* Tn7 sites in their genomes. For transposition both *L* and *R* terminal repeats are required. Elements with two *L* repeats do not move whereas two complete *R* termini can assure insertion to *att* Tn7 sites. Tn7, because of the site specificity, is not very useful for insertional mutagenesis, but it has an advantage of inserting genes at the standard map position. Tn7 inserts preferentially in the vicinity of triple-helical sites. The Tn7 family of transposons includes Tn73, Tn1824, and Tn1527 with substantial similarity or even identity. Tn1825 is a clearly distinct member. ▶transposons bacterial, ▶transposable elements, ▶triplex; Craig N 1989, p 211. In: Mobile DNA. Berg DE, Howe MM (Eds.) Amer Soc Microbiol, Washington, DC.

Tn10: A bacterial (*E. coli*, *Klebsiella*, *Proteus*, *Salmonella*, *Shigella*, *Pseudomonas*, etc.) transposable element of 9.3 kb. It may move within a bacterial

genome, from the bacterial chromosome to a temperate phage or plasmid and among different bacterial species. Its overall structure can be represented as in Figure T64.

The boxed left insertion element *IS10* (L) is a defective transposase. The boxed right *IS10* element (R) is a functional transposase (see Fig. T64). Thus *Tn10* is a composite transposable element. The *tetR*, *A*, *C* and *D* genes are involved in resistance against tetracycline. The *tetR* is a negative regulator and *tetA* encodes a membrane protein. The arrows indicate orientation and direction of transcription. The promoter of the *IS10* element may serve as promoter for adjacent outside genes (pOUT).

Insertion of *Tn10* within a gene, operon or upstream regulatory element may abolish the activity of the gene(s) or may modify their transcription. In the so-called polar insertions transcription is initiated within the *Tn* element but it may be terminated when rho signals are encountered. In the nonpolar insertions there are no rho sequences downstream to halt transcription. This type of *read-through* transcription may only take place in some *Tn10* derivatives but not in the wild type element. The rate of transposition for *IS10* is 10^{-4} and for *Tn10*, 10^{-7} per cell cycle.

Both the *IS10* and the *Tn10* elements can cause chromosomal rearrangements (see Fig. T65). Insertion and transposon sequence may show the portable region of homology and can undergo homologous recombination (see Fig. T66). These recombinations may generate deletions between, or inversions in, the regions in-between them at rates two orders of magnitude less frequent than transposition or lead to the formation of cointegrates.

All DNA segments flanked by *IS10* can become transposable and thus may represent new composite

transposons. *IS10* and *Tn10* may assist the fusion of different replicons and transfer information between bacterial chromosomes, plasmids, and phages. The transpositions may also generate new units of regulated gene clusters by the movement of structural genes under the control of other regulatory sequences.

The excision of the transposon may be “precise” if the nucleotide sequence is restored to its pre-insertion condition. Precise excision (average frequency 10^{-9}) may remove one copy of the 9-bp target site inverted duplications.

The “near-precise excision” events involving removal of most of the internal sequences of *Tn10* occur at a frequency of about 10^{-6} and may later be followed by precise excision of the remaining sequences. These non-transposase mediated events are also independent from the host RecA recombination functions. Precise excision is mediated by RecBC and RecF pathways. *Tn10* and *IS10* may transpose either by a non-replicative or a replicative mechanism. In the former case, the whole double-stranded element is lifted from its original position and transferred to another site. In the second case, only one of the old strands of the transposon is integrated into the new position and the other strand represents the newly replicated one.

At the target site apparently two staggered cuts are made, 9 bases apart. This causes then the 9 bp target duplications when the gap is filled and the protruding ends are used as templates Figure T67.

The transposon (ca. 46 kDa) is coded within the *IS10* right terminus by about 1,313 nucleotides. The frequency of transposition may increase up to five orders of magnitude by increasing the expression of the transposase. The transposase action prefers being

Figure T64. Structure of *Tn10*

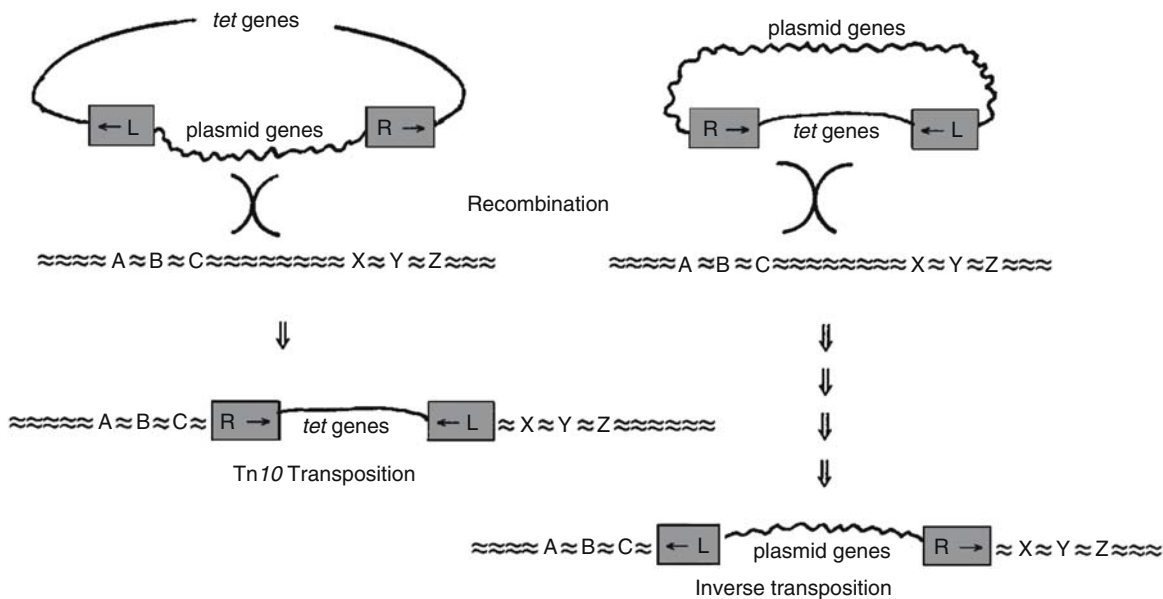

Figure T66. Tn10 transpositions. Left: the normal event, at right: the inverse transposition (or inside-out) transposition. Some other events may also lead to deletions or deletions and inversions. The L and R boxes represent Tn10 termini. The thin line stands for the transposon sequences whereas the single jagged line indicates the sequences flanking the transposon in the original location of the plasmid. The ≈≈≈ symbolizes the DNA sequences of the target

Figure T67. Target expansion

in the vicinity of the transposed sequences and its action is reduced by distance. Also, longer transposons are moved less efficiently than shorter ones. Each kb increase in length involves about 40% reduction in movement within transposon sizes 3 kb to 9.5 kb. Proteins IHF, HU and DNA gyrase also regulate transposition. The transposition frequency may also be modified (within three orders of magnitude) by the chromosomal context, i.e., cis-acting sequences. The integration hot spots appears to have some consensus sequences within the 9 bp target site in three bases (see Table T1).

Transposition seems to avoid being actively transcribed and thus the most essential genes of the

recipient. The transposase gene is transcribed from a very low efficiency pIN promoter origin-ating near the *O* end of the right *IS* element. The divergent pOUT promoter opposes its transcription also. Apparently, on average, each cell generation may not produce one molecule of transposase. Two *dam* (adenine) methylation sites (GATC) are located within pIN and the activity of this promoter is facilitated in the absence of methylation by the host *dam* methylase (located in *E. coli* at 74 min). Actually, the transposase promoter is usually hemi-methylated. An increase in the number of Tn10 copies per cell reduces transposase activity because the pOUT promoter generates an antisense RNA transcript that may pair to a 35-base complementary region of the pIN promoter region. The transposase activity is also regulated by fold-back inhibition (FBI), hindering the attachment of the Shine-Dalgarno sequence of the transcript to the ribosome. The Tn10 system is protected from transposase activation by inhibition of read-through.

Transposons inserted into a particular gene cause mutations because of the disruption in the continuity

of the coding sequences. Transposon mutagenesis has considerable advantage over chemical or radiation mutagenesis because it induces mutation only at the site of insertion while chemicals may affect several genes simultaneously. In addition, mutagenesis with *Tn10* labels the gene by tetracycline resistance, an easily selectable marker. Transposons may also label foreign genes cloned in *E. coli* or *Salmonella*. The tetracycline-resistance gene has been extensively used for monitoring insertions that result in the loss of tetracycline resistance but retain other (selectable) markers in the cloning vector. ▶IHF, ▶HU, ▶gyrase, ▶antisense RNA, ▶FBI site, ▶readthrough, ▶transposable elements bacteria; Craig N 1989 Mobile DNA. Tn Syndrome: A rare autoimmune disease involving exposure on the surface of erythrocytes, platelets, granulocytes, and lymphocytes of the normally hidden Tn antigen. In patients, both Tn+ and Tn- hematopoietic cells show up and leukemia, thrombocytopenia and nephropathy appear. The Tn membrane glycoprotein is incompletely glycosylated. The altered Tn loses a terminal galactose due to a defect in the T-synthase enzyme, encoded at 7p14-p13. A somatic mutation in the Xq23 gene, COSMC, alters a molecular chaperone required for the proper folding of the enzyme. (See Vainchenker W et al 1985 J Clin Invest 75:541; Ju T, Cummings RD 2005 Nature [Lond] 437:1252).

TNA: (L)- α -Threo-furanosyl-(‘-2’)-oligonucleotides. These molecules contain 4-carbon (tetrose) sugars rather than pentose and are capable of pairing with RNA and DNA.

TncRNA (tiny noncoding RNA): ▶RNA noncoding

TNF (tumor necrosis factor): Proteins ($M_r \approx 17$ K) that are selectively cytotoxic or cytostatic to the cancer cells of mammals. They are relatively harmless to normal cells by being lymphokines. They are defense molecules against intracellular pathogens. The TNF family includes diverse transmembrane proteins with high homology in the receptor-binding regions. TNF was originally discovered in rodent cells infected by bovine *Mycobacterium* and then with endotoxin. The serum of these animals produced hemorrhagic necrosis and occasionally complete regression of transplanted tumors. The mature human TNF α consists of 157 amino acids after trimming off 73 amino acids from the pre-TNF. It has receptor sites on the surface of tumors and its action is synergistic with γ interferon. TNF α and TNF β have similar functions and display $\approx 30\%$ homology. TNF α plays a promoting role in obesity and inflammatory metabolic diseases (diabetes, atherosclerosis, hypertension,

asthma, osteoarthritis, cancer, etc.). TNF α inhibitors are used for antiinflammation (rheumatoid arthritis) therapy. The relatively small molecule, trifluoromethylphenyl indole, causes a very high (600-fold) dissociation of the trimeric structure of TNF α . This observation may be exploited for the development of new drugs (He MM et al 2005 Science 310:1022).

The two TNF genes each have 3 introns in their 3 kb sequence. In mice, it is localized within the *H-2* (histocompatibility cluster) and in humans in the homologous *MHC* region in chromosome 6p23, either between HLA-DR and HLA-A or proximal to the centromere. The genes were cloned and sequenced in the mid-1980s. TNF α and IL-1 are the major inflammatory cytokines whereas IL-10 and TGF β , IL-R and TNF-R are anti-inflammatory. TNF is produced mainly by macrophages. A TNF β deficiency may increase chromosomal instability and may lead to cancerous transformation. The tumor necrosis family of proteins includes FASL, CD40L, LT and β , CD30L, CD27L, 4-1BBL, OX40L, TRAIL, OPGL, LIGHT, APRIL, and TALL. Estrogen deficiency and ovariectomy stimulate osteoclastogenesis (bone loss) by T cell-produced tumor necrosis factor (TNF α). This process is mediated by enhanced production of interleukin-7 (Ryan MR et al 2005 Proc Natl Acad Sci USA 102:16735). ▶lymphokines, ▶cytokines, ▶endotoxin, ▶hemorrhage, ▶necrosis, ▶interferons, ▶histocompatibility, ▶HLA, ▶TNF-R, ▶TRAF, ▶Crohn's disease, ▶arthritis, ▶macrophage, ▶TACE, ▶TACI, ▶TNFR, ▶TRAIL, ▶NGF, ▶lymphotoxin, ▶LT α , ▶HVEM, ▶transposase, ▶IL-7, ▶IL-32, ▶asbestos; Kassiotis G, Kollias G 2001 J Clin Invest 107:1507; Liu Y et al 2003 Nature [Lond] 423:49; review of inflammation and diseases: Hotamisligil GS 2006 Nature [Lond] 444:860.

TNFR (tumor necrosis factor receptor, p55, p75): Similar receptors in both animals and plants may be involved in processes of differentiation. TNFR-1 and -2 are distinguished; TNFR-1 mediates different effector functions through separate pathways. The intracellular portion of TNFR-1 contains a 70-amino acid death domain, which mediates signals for apoptosis and the activation of NF- κ B. TNF binds to the extracellular domain of TNFR-1 resulting in its trimerization. The TNF1 attracts the adaptor TRADD (tumor necrosis factor receptor associated death domain) and TRAF2 and TRAF1. Subsequently, the TNFR1 recruits FADD (Fas associated death domain). TRAF2 (tumor necrosis factor associated protein 2) is contacted by TRAF1 and RIP (receptor interacting protein). This complex then signals for apoptosis, JNK/SAPK and NF- κ B activation. Protein SODD (457-amino acid silencer of death domains)

is expressed in all human tissues and interacts with the intracellular domain of TNFR-1 but not with TNFR-2, TRADD, FADD or RIP, and interferes with all TNF signaling through TNFR-1. JNK does not participate in the apoptotic pathway and the activated NF- κ B works against apoptosis though inflammation may result. ▶TNF, ▶TRAF, ▶NF- κ B, ▶nitrogen fixation [ENOD], ▶apoptosis, ▶Jun, ▶Fas, ▶NGF, ▶Paget's disease, ▶APRIL, ▶BAFF, ▶Blys; Locksley RM et al 2001 Cell 104:487.

TNT: A solution containing 10 mM Tris.HCl buffer (pH 8.0), 150 mM NaCl, 0.05% Tween 20.

Toad: *Bufo vulgaris*, 2n = 36; *Xenopus laevis*, 2n = 36 (see Fig. T68). ▶frogs

Figure T68. Toad

TOASTS: Traced orthologous amplified sequence tags.

Tobacco (*Nicotiana* spp): The smoking tobacco is an allotetraploid (*N. sylvestris* \times *N. tomentosiformis*) 2n = 48. The basic chromosome number generally is x = 12; however, diploid forms with 2n = 20 (*N. plumbaginifolia*) and 2n = 18 (*N. langsdorffii*), and in the *Suavolens* group, 2n = 36 (*N. benthamina*), 2n = 46 (*N. caviola*), 2n = 32 (*N. maritima*), 2n = 36 (*N. amplexicaulis*), 2n = 40 (*N. simulans*), 2n = 44 (*N. rotundifolia*) are also found. For genetic studies the diploid species are most useful (*N. plumbaginifolia*). For transformation, *N. tabacum* is used most commonly because of the easy regeneration of plants from single cells. Antibiotic resistant chloroplast mutations are available. The S strain is a streptomycin

resistant mutant of the variety Petite Havana. Mutation, recombination and transformation techniques are available for its plastid genome, using primarily antibiotic resistant ctDNA mutations. ▶*Nicotiana*, ▶smoking

Tobacco Mosaic Virus: ▶TMV

Tobacco Necrosis Virus (TNV): An icosahedral single-stranded RNA virus of \approx 4 kb. It is a root plant pathogen. ▶icosahedral

Tobacco Satellite Necrosis Virus (TSNV): A 17 nm diameter, single-strand RNA (\approx 1.2 kb) virus that depends on TNV for its replication. ▶tobacco necrosis virus

Tocopherol α (vitamin E): Tocopherol, α deficiency results in nutritional muscular dystrophy and sterility, although, normally, humans with regular diet do not show any need for it. Vitamin E may be beneficial as it is an antioxidant and regulates nerve functions and atherosclerosis. Vitamin E is a lipid-soluble molecule and plant oils are a major source. ▶vitamin E, ▶atherosclerosis

T-Odd Virus: Bacteriophages with odd number designations such as T3, T5, T7, etc. ▶bacteriophages

Toeprinting: A procedure for mapping the translation initiation ternary complex (EI1A•GTP•tRNA) to the ribosome. In one approach, a 32 P-labeled oligonucleotide is annealed to the mRNA, downstream (3') from the presumed site of initiation, and reverse transcriptase is used for the extension of the radioactive primer up to the position of the bound ribosome where the chain growth stops. Various types of purification may be used for the isolation and identification of the initiation complex. ▶elongation factors, ▶protein synthesis, ▶ribosomes, ▶mRNA surveillance; Ringquist S, Gold L 1998 Methods Mol Biol 77:283; Dmitriev SE et al 2003 FEBS Lett 533/C:99.

TOFMS (time-of-flight mass spectrophotometry): A powerful technique used for the analysis of the primary structure of proteins. ▶mass spectrum, ▶matrix-assisted laser desorption time of flight mass spectrometry, ▶MALDI; Verentchikov AN 1994 Anal Chem 66:126; She Y-M et al 2001 J Biol Chem 276:20039.

TOGA (total gene expression analysis): A completely automated technology for the simultaneous analysis of the expression of nearly all genes. Basically, it selects a four-base recognition endonuclease site and an adjacent four nucleotide parsing sequence (a syntactical determinant, e.g., for *MspI* CCGGN₁N₂-N₃N₄) and their distance from the 3'-end of an mRNA (from the polyA tail). These generate a specific, single identity label for each mRNA. The

parsing sequences also serve as parts of the PCR primer-binding sites in 256 PCR-based assays, which determine the presence and concentration of that mRNA in a tissue. ►microarray hybridization, ►SAGE, ►RNA fingerprinting; Sutcliffe JG et al 2000 Proc Natl Acad Sci USA 97:1976; expanded TOGA: <http://www.tigr.org/tdb/tgi/ego>.

TOGA (Tiger Orthologous Gene Alignment): A database generated by pair-wise comparison between tentative consensus sequences in different organisms: <http://www.tigr.org/tdb/tgi.shtml>.

Togavirus: RNA plus strand viruses of about 12 kb. The capsid proteins are synthesized only after completion of replication. This viral family includes rubella, yellow fever, and encephalitis viruses. ►RNA viruses, ►plus strand

Toggle Switch, Genetic: ►Gene-Switch cassette, ►synthetic biology

Toilet: The medical meaning is cleansing, clearing.

Tolerance of antibiotics: The infectious organism does not die but stops reproducing. ►antibiotic resistance

Tolerance, Immunological: Non-reactivity to an antigen that under other conditions would evoke an immune response. Antigens provided to fetuses or neonates with immature immune systems can induce tolerance. In adults, a very high or very low dose of the antigen may cause tolerance. The tolerance is the result of either clonal elimination or inactivation of lymphocytes in the thymus. Liver transplantation may induce systemic immune tolerance for certain (kidney, heart) allografts. ►lymphocytes, ►immune response, ►antigen, ►allograft, ►immunosuppressants; Gaunt G, Ramin K 2001 Am J Perinatol 18(6):299; Salih HR, Nussler V 2001 Eur J Med Res 6(8):323; Chang CC et al 2002 Nature Immunol 3:237.

Tolerization: CD4⁺ CD25⁺ T cells secure tolerance to organ-specific self-antigens. The Foxp3 transcription factor mediates the process and its defect cause immune reaction in humans and mice. Elimination of these factors is tolerization of both autoreactive and alloreactive lymphocytes. This may be a precondition to successful stem cell therapy. ►T cell, ►B cells, ►immune reaction, ►autoimmune diseases, ►FKH, ►stem cells

Toll (*Drosophila*, 3–91, human homolog TRAF6): Toll encodes a signaling protein operating through the NF-κB receptor in both the fly and humans, and the MyD88 adaptor protein mediates it. For the activation of NF-κB, IRAK (interleukin associated receptor kinase) and the TRAF6 (tumor necrosis factor associated receptor) protein, activated by IL-1, are required. This pathway is essential for the immune

system. The human Toll-like receptors (hTLR) are transmembrane glycoproteins that respond to bacterial lipoproteins (TLR2), lipopolysaccharides (TLR4), unmethylated CpG-DNAs (TLR9), etc., with activation of apoptosis, bacterial killing, tissue injuries and the induction of the innate immune response (Beutler B 2004 Nature [Lond] 430:257). The toll-like receptors TLR7 and TLR8 mediate the recognition of guanine and uridine-rich single-stranded RNA oligonucleotides, which stimulate dendritic cells and macrophages to secrete interferon-α and cytokines (Hell F et al 2004 Science 303:1526). The Toll-like receptor includes recognition sites for the innate immune system. TLRs signal through TRAF3 and TRAF6 effectors (Häcker H et al 2006 Nature [Lond] 439:204). TLR receptor signaling may not be required for adjuvant-enhanced antibody response as thought earlier (Gavin AL et al 2006 Science 314:1936). The *Toll/spaetzle/cactus* gene cassette is involved in the control of the antifungal peptide, drosomycin production. ►morphogenesis {52} in *Drosophila*, ►IRAK, ►TRAF, ►IL-1, ►IL-12, ►MyD88, ►NF-κB, ►ATF3, ►apoptosis, ►CD14, ►innate immunity, ►antimicrobial peptides, ►pattern recognition receptors, ►inflammation; Kobayashi K et al 2002 Cell 110:191; Pasare C, Medzhitov R 2003 Science 299:1033; Takeda K et al 2003 Annu Rev Immunol 21:335; crystal structure of TLR3: Choe JH et al 2005 Science 309:581; toll receptors: Gay NJ, Gangloff M 2007 Annu Rev Biochem 76:141.

Tolloid: ►bone morphogenetic protein

TOM (transfer outer membrane): A protein complex that regulates transport through the outer layer of the mitochondrial membrane. ►mitochondria, ►TIM

Tomato (*Solanum lycopersicum*, 2n = 24): The tomato has about 8–10 related species. It is one of the cytologically and genetically best-known autogamous plants and is suitable for practically all modern genetic manipulations. Its genome size is bp/n ≈ 6.6 × 10⁸. ►coffee; for gene index: <http://www.tigr.org/tdb/tgi.shtml>; <http://zamir.sgn.cornell.edu/mutants/>; expression database: <http://ted.bti.cornell.edu/>; EST database: <http://biosrv.cab.unina.it/tomatestdb>.

Tomato Bushy Stunt Virus: A single-strand RNA virus of about 4,000 bases enveloped by an icosahedral shell consisting of 180 copies of a 40-kDa polypeptide. ►icosahedral

Tomography (body section radiography): Tomography is conducted by a tomograph in which a source of X-radiation moves in the direction opposite to that of a film, recording the image clearly only in one plane and blurring the remaining images. In computerized

axial tomography (CAT scan), the scintillations produced by the radiation are recorded on a computer disk and the cross section of the body is analyzed electronically. Positron emission tomography (PET) involves the use of positron-labeled metabolites (e.g., γ -ray emitting glucose) (see Fig. T69). Along the path of the radiation, positrons and electrons collide and the local concentration of the isotopes is recorded electronically. Electron tomography permits the three-dimensional reconstruction of cells, organelles, and supramolecular assemblies (Luci  V et al 2005 *Annu Rev Biochem* 74:833). Single-photon emission computed tomography (SPECT) takes γ -ray photographs around the body and a computer reconstructs three-dimensional images resulting in great resolution even of overlapping organs. Optical coherence tomography (OCT) resolves details in tissues at 1–15 μm in situ and it is thus one to two orders of magnitude finer than the ultrasound (Fujimoto JG 2003 *Nature Biotechnol* 21:1361). Ultrasonic tomography uses ultrasound scanning. The radiation may not be without risk (L brich M et al 2005 *Proc Natl Acad Sci USA* 102:8984). Gene expression tomography uses sliced brain sections in a cryostat. It obtains three-dimensional images of the expression pattern of particular genes using axial rotation (Brown VM et al 2002 *Physiol Genomics* 8:159). The RNA transcripts may be amplified by quantitative reverse PCR. ►X-rays, ►ultrasonic, ►sonography, ►nuclear magnetic resonance spectroscopy, ►imaging, ►RT-PCR; Czernin J, Phelps ME 2002 *Annu Rev Med* 53:89; Cristofallini M et al 2002 *Nature Rev Drug Discovery* 1:415.

Figure T69. Pet scan of the brain; note different activity area at the arrow

Tongue Rolling: A human hereditary trait. Although it is frequently considered to be dominant, its inheritance is somewhat complex. Sturtevant AH (1940 *Proc Natl Acad Sci USA* 26:100) discovered it; he was the same person who first constructed a map of genes on a chromosome. Identical twins may be discordant for

the trait (Matlock P 1952 *J Hered* 43:24). This trait seems to also be associated with moving the ears.

Tonoplast: An elastic membrane ($\approx 8\text{ nm}$) that surrounds the vacuoles. Several proteins control the traffic through this membrane. ►vacuoles; Maeshima M 2001 *Annu Rev Plant Physiol Plant Mol Biol* 52:469.

Tooth (pl. teeth): See the Figure T70. The crown (at top) is covered by enamel and it is remodeled after eruption. The cusp pattern varies in different species and it is regulated by an ectodin protein, secreted as an inhibitor of bone morphogenetic protein (see Fig. T70) (Kassai Y et al 2005 *Science* 309:2067). Teeth and bone DNA, present in small quantities, can be amplified by PCR and used for the analysis of forensic and ancient samples (Alonso A et al 2001 *Croatian Med J* 42:260; Kemp BM, Smith DG 2005 *Forensic Sci Int* 154:53). High-resolution micro-computed tomography permits detection of small differences in adult tooth morphology that are determined easily in embryonic development. Such a technology detected that the molars of Neanderthals grew very much the same way as in modern humans (Macchiarelli R et al 2006 *Nature [Lond]* 444:748). ►bone morphogenetic protein, ►tomography; gene expression in tooth: <http://bite-it.helsinki.fi/>.

Figure T70. Posterior tooth of vertebrate

Tooth Agensis: Tooth agenesis is caused by a dominant (chromosome 4p) mutation in the homeodomain of transcription factor MSX1. It involves failure to form the second premolars and the third molars. Tooth development is under the control of many genes. Among them fibroblast growth factor (FGF) and bone morphogenetic (BMP) play pivotal and multiple roles. FGF and BMP regulate MSX1 and PAX9 transcription factors. ►homeodomain, ►Rieger syndrome, ►amelogenesis imperfecta, ►FGF, ►BMP, ►PAX, ►MSX1, ►oligodontia, ►hypodontia

Tooth Development: ▶[anodontia](#); Tucker A, Sharpe P 2004 *Nature Rev Genet* 5:499.

Tooth Malposition: Apparently, an autosomal dominant gene controls the various misplacements or underdevelopment of the incisors and the canine teeth. ▶[Hallermann-Streiff syndrome](#), ▶[Jackson-Lawler syndrome](#), ▶[amelogenesis imperfecta](#), ▶[cherubism](#)

Tooth Size: The tooth size appears to be influenced by the human Y chromosome as indicated by observations on various sex-chromosomal dosages.

Tooth-and-Nail Dysplasia (Witkop syndrome, TNS): In tooth-and-nail dysplasia, most commonly, the incisors, canine teeth and some of the molars are not or poorly developed. In some cases the condition is accompanied with abnormal toenails in children. Mutations at an MSX1 (4p161) subunit—a transcriptional repressor—seem to account for the phenotype. ▶[hypodontia](#), ▶[Hallermann-Streiff syndrome](#), ▶[dental no-eruption](#), ▶[dentin dysplasia](#), ▶[denticle](#), ▶[MSX1](#); Jumlogras D et al 2001 *Am J Hum Genet* 69:67.

5'-TOP (5'-terminal oligopyrimidine tract): mRNAs are part of the protein synthetic machinery and they are translated under the control of S6 kinases that are targets of insulin signaling in mammals. Cell growth (not cell division) is controlled by this process. ▶[S6](#), ▶[insulin-like growth factors](#); Crosio C et al 2000 *Nucleic Acids Res* 28:2927.

Top Agar: An agar solution of ~0.6% generally containing 0.5% NaCl and some organic supplements. About 2 mL of the solution, with suspended bacterial cells, is spread over the agar medium (30 mL/10 cm Petri plates) to initiate selective bacterial growth, e.g., in Ames tests. ▶[Ames test](#)

Top-Down Analysis: Starting with a mutant phenotype, the physiological or molecular mechanism responsible for the alteration is investigated. In contrast, the bottom-up analysis first studies the molecules and then the analysis is extended to their relationships to the phenotype. Currently, the major endeavor is to go beyond the role of individual molecules and major interest is being focused on the critical domains of the molecules. ▶[reversed genetics](#)

Top-Down Mapping: Top-down mapping uses either traditional genetic recombinational analysis or radiation hybrid maps. ▶[mapping genetic](#), ▶[radiation hybrids](#), ▶[bottom-up map](#)

Topical Reversion: The back mutation is the result of alterations within the gene rather than due to extragenic suppression. ▶[reversion](#), ▶[suppressor extragenic](#), ▶[suppressor intragenic](#)

Topoisomerase (TOP): Topoisomerases are enzymes which alter the tertiary structure of DNA without a

change in the secondary or primary structure. The monomeric topoisomerase I (10q12-q13.1) nicks and closes single strands of DNA and changes the linking number in one strand. The dimeric topoisomerase II can cut and reattach both strands of the DNA and affect linking number in both strands.

Topoisomerase II (17q21-q22) disentangles DNA strands and plays an important role in DNA replication, transcription and recombination, suppression of mitotic recombination, stabilization of the genome (chromosome breakage), regulation of supercoiling, eukaryotic chromosome condensation, control of segregation of the chromosomes, regulation of the cell cycle, and nuclear localization of imported molecules. The mitochondrially located Top1mt is encoded at 8q24.3. Topoisomerases are important objects in cancer therapy research. Charvin G et al 2005 (cited in the caption in Figure T71), outlines mechanisms of action of the different topoisomerases. The prokaryotic topoisomerases I—in contrast to the eukaryotic ones—require Mg^{2+} and single-stranded DNA segments and relax only the negatively supercoiled molecules. TOP I activity is required for the proper segregation of prokaryotic chromosomes (Zhu Q et al 2001 *Proc Natl Acad Sci USA* 98:9766) and has been located to human chromosome.

Figure T71. Redrawn after Charvin G et al 2005 *Annu. Rev. Biophys. Biomol. Struct.* 34:201

The human topoisomerase I consists of 765 amino acids. Prokaryotic DNA topoisomerase III supports the movement of the DNA replication fork and can also function as an RNA topoisomerase and can interconvert RNA circles and knots. The eukaryotic topoisomerase III (17p12-p11.2) is homologous with prokaryotic topoisomerase. Mice with knocked-out DNA topoisomerase III β are viable but senesce earlier and have about a 40% shorter life span. Chromosomal abnormalities in *top3 β ^{-/-}* mice might lead to a persistent increase in apoptotic cells, which

might in turn lead to the progression of autoimmunity (Kwan KY et al 2007 Proc Natl Acad Sci USA 104:9242). ▶DNA replication, ▶gyrase, ▶linking number, ▶linking number paradox, ▶mtDNA, ▶camptothecin, ▶p53; Wang JC 1996 Annu Rev Biochem 65:635; Changela A et al 2001 Nature [Lond] 411:1077; Champoux JJ 2001 Annu Rev Biochem 70:369; Wang JC 2002 Nature Rev Mol Cell Biol 3:430; evolution of topoisomerases: Forterre P et al 2007 Biochimie 89:427; topoisomerases as therapeutic targets of infection: Tse-Dinh YC 2007 Infect Disord Drug Targets 7:3; see Fig. T72.

Figure T72. The 67-kDa fragment of DNA topoisomerase I of *E. coli* displaying major domains and nucleotide-binding sites. (From Feinberg H, Changela A, Modrigón A 1999 Nature Struct. Biol. 6:961)

Topological Filter: The topological filter is synonymous with two-step synopsis. The assumption is that synopsis requires an interaction between DNA *res* sites and the three subunits of a resolvase enzyme (step 1). After this initial step, the II and III subsites of the resolvase-*res* dimers pair in a parallel manner and the subunits interwrap. Then, the two I subsites of the resolvase dimer bind resulting in a productive synaptic complex (Step 2), capable of initiating DNA change. ▶synopsis, ▶res, ▶resolvase; Watson MA et al 1996 J Mol Biol 257:317.

Topological Isomers of DNA: ▶linking number

Topomap: A topomap displays genes that show correlated expression across a large set of microarray experiments.

Toponome: A single-cell-localized organization of proteins, carbohydrates, lipids, and nucleic acids. ▶MELK, ▶genetic networks

TORC (transducer of regulated CREB): A coactivator of CREB, a CRE (cyclic AMP-response element) binding protein. The glucose level is regulated in animal cells by insulin and glucagons, and TORC plays a central role in the homeostasis of glucose levels as outlined in the oversimplified chart (see Fig. T73). ▶gluconeogenesis, ▶CRE, ▶glucagons, ▶diabetes, ▶cAMP, ▶PKA, ▶CREB, ▶AMPK; Koo S-H et al Nature [Lond] 438:1109.

Figure T73. When TORC-2 is dephosphorylated gluconeogenesis genes are turned green in the nucleus. When TORC-2 is phosphorylated gluconeogenesis is attenuated

TORF: An open reading frame identified with the aid of a transposon. ▶ORF, ▶transposon

TORs (target of rapamycin): TORs are phosphatidylinositol kinases of yeast (TOR1, TOR2). They are also called RAFT1 and FRAP. TORs convey resistance to FKBP. The C-terminal domains of the TOR family are homologous to the catalytic domain of PI(3)K. TORs block the turnover of nutrient transporters, autophagy, and the interphase of the cell cycle but promote protein kinase C signaling, actin and cytoskeleton organization, and tRNA and ribosome formation, transcription and translation. TOR may be involved in the regulation of life span of *Drosophila* through affecting nutrition (Kapahl P et al 2004 Current Biol 14:885). The movement of TOR from the cytoplasm to the nucleus is controlled by the nutritional status in yeast (Li H et al 2006 Nature [Lond] 442:1058). The TORC1 complex is sensitive to rapamycin but the TORC2 is not. TORC1 positively regulates ribosome biogenesis, translation and nutrient import and blocks stress-responsive transcription. TORC2 mediates cell growth through actin organization (Wullschlegel S et al 2006 Cell 124:471). TORs play a central role in the regulation of several human diseases such as hamartomas and other hypertrophic diseases (Inoki K et al 2005 Nature Genet 37:19). ▶rapamycin, ▶PIK, ▶FK506, ▶PI[3]K, ▶S6K, ▶autophagy, ▶cell cycle, ▶aging, ▶cytoskeleton, ▶protein kinases, ▶cisplatin, ▶Akt, ▶leukemia; Schmelzle T, Hall MN 2000 Cell

Tormogen: A component cell of the bristle that secretes the bristle socket. The other bristle cells are the trichogens that secrete the bristle shaft, also a neuron, which contacts the shaft and through its axon connects with the nervous system.

Toroid/Toroidal: A body or surface generated by the rotation of a plane curve or circle. It may assume the shape of a ring/doughnut or may resemble a barrel. ▶torus; Hud NV, Vilfan UD 2005 Annu Rev Biophys Biomol Struct 34:295.

Torpedo Model: ▶transcription termination in eukaryotes

Torsion Dystonia: ▶idiopathic torsion dystonia, ▶dystonia

Tortoiseshell Fur Color: Develops in female (cats) heterozygous for the X-chromosome-linked genes black and yellow colors because of selective, alternate inactivation of the two mammalian X-chromosomes. The tortoiseshell animals have mixed patches of black and yellow fur (Fig. T74). These fur patterns occur in the XX (female) or exceptionally in the XXY Klinefelter male cats. (See Lyon hypothesis, lyonization, calico cat).

Figure T74. Back of a tortoiseshell cat

Torus: A ring-shaped emergence, swelling, or a bordered pit. ▶toroid

Totipotency: A characteristic of zygotic cells that permits differentiation into any type of cell or structure, including the whole organism. Initially, the paternal genome of animals is highly condensed and it is bound by protamines, which are replaced by histones before the S phase. Histone H3.1 is, however, absent from the paternal genome before DNA replication. The paternal genome displays H3K4me1, H3K9me1, and H3K27me1 (single-methylated lysines) but their dimethylation is largely postponed after DNA replication. The paternal genome is demethylated globally but not the maternal genome. For totipotency, the maternal transcription factors Oct3/4, Sox2, and the Polycomb group proteins are essential. By the two-cell stage the differences diminish yet the blastomeres maintain totipotency to the eight-cell stage. Between the eight and 16-cell stages polarization is initiated and this signals a switch to transition and to pluripotency. From pluripotency, totipotency is reestablished by the differentiation of the germline from the soma. These processes require numerous genetic and epigenetic factors (Surani MA et al 2007 Cell 128:247).

In the germline of *Caenorhabditis* the expression of translational regulators is required for the maintenance of totipotency. In *mex-3* and *gld-2* double mutants, germ cells transdifferentiate into somatic cells of muscles and neurons (Ciosk R et al 2006 Science 311:851). Plant cells maintain their totipotency in diverse adult tissues and after dedifferentiation may initiate other types of differentiations and of somatic cells entire organisms may be regenerated in cell cultures. Totipotency of animal cells is much more limited although lower animals such as hydra and earthworms may regenerate from differentiated tissues. The embryonic stem cells (ES) of mouse come close to totipotency/pluripotency inasmuch as they can be transferred to mouse embryos and can contribute to the formation of various cell types, including the germline. After special treatments, differentiated animal cells may also revert to stem cell status. ▶morphogenesis, ▶somatic embryogenesis, ▶redifferentiation, ▶multipotent, ▶pluripotency, ▶ES, ▶nuclear transplantation, ▶stem cells

Touch-and-Go Pairing: The end-to-end synapsis of the sex chromosomes in the heterogametic sex of some insects (see Fig. T75).

Figure T75. Touch-and-go-pairing. After Schrader F 1940 Proc Natl Acad Sci USA 26:634

Touch-Down PCR: ►hot-start PCR

Touch-Sensitivity: In mammals, the brain sodium channel BNC1 mediates touch sensitivity. ►degenerin; Welsh MJ et al 2002 J Biol Chem 277:2369.

Toulouse-Lautrec, Henri (1864–1901): One of the most remarkable painters of the end of nineteenth-century Paris life. He was a colleague of van Gogh and an influential precursor of modern art and was thought to suffer from pycnodysostosis. His parents were first cousins. This diagnosis of his genetic malady has been questioned [Nature Genetics 11:363], and it appears that deficiency of cathepsin K might have been involved. ►pycnodysostosis, ►cathepsins

Tourette's Syndrome (Gilles de la Tourette disease, GTS): A human behavioral anomaly causing motor and vocal incoordination (tic, twitching), stuttering (echolalia), the use of foul language (coprolalia), obsessions, and hoarding. The onset is between 7 to 14 years of age and three-fourths of those affected are male. The genetic determination is apparently dominant with incomplete penetrance and expressivity. Male:female ratio of 4.3:1 has been reported. Genes in several chromosomes (4q, 5q, 8p, 18q, 7q, 9, 3, 11q23, 17q) have been implicated. 238 nuclear families yielding 304 “independent” sibling pairs and 18 separate multigenerational families, for a total of 2,040 individuals using whole-genome screen for 390 microsatellite markers, indicated strong linkage for a region on chromosome 2pA (Tourette Syndrome Assoc. Internat. Consort. Genet 2007 Am J Hum Genet 80:265). A paracentric inversion involving chromosome 18q22 causes delayed replication in a sequence across at least 500 kb (State MW et al 2003 Proc Natl Acad Sci USA 100:4684). A sequence variant in Slit and Trk-like1 (SLITRK1)—encoding a single-pass transmembrane protein—has been identified at 13q31.1 (Abelson JF et al 2005 Science 310:317).

The frequency of the defective gene(s) was estimated to be 0.4 to 0.9%, and a prevalence of 1 to 0.02% has been observed in different populations. Some of the mild cases are suspected to be responsible for male alcoholism and female obesity. The expression of the condition is frequently much influenced by the environment. ►affective disorders; Zhang H et al 2002 Am J Hum Genet 70:896.

Townes-Brocks Syndrome (SALL1, 16q12.1): A highly variable dominant malformation with good penetrance. The symptoms include imperforate anus, polydactyly, syndactyly, abnormal earlobes, hearing deficit, kidney and heart anomalies, and mental retardation. The majority of the individuals display mutation in the SALL gene encoding a 1,325 amino acid protein with double Zn-finger domains. The normal protein is a transcriptional repressor and it is

associated with heterochromatin. ►penetrance, ►Zinc finger, ►heterochromatin; Netzer C et al 2001 Hum Mol Genet 10:3017.

Toxic Shock Syndrome: TSS is caused by infection of *Staphylococcus aureus*/*Streptococcus pyogenes* Gram-positive bacteria. It affects, primarily, menstruating women. It begins with sudden high fever, vomiting, diarrhea, and muscle pains (myalgia). Later, rash, hypotension, and potentially death may follow. Although septic shock has been attributed mainly to the cell wall lipopolysaccharides (present in Gram-negative bacteria) and peptidoglycan and lipoteichoic acid (present in Gram-positive bacteria), actually the unmethylated 5'-CpG-3' prokaryotic DNA may be responsible for the immune reaction. These bacterial superantigens (SAG) bind directly to the class II histocompatibility complex on the antigen-presenting cells and to specific variable regions of the β -chain of the T cell receptor and evoke very severe response. Plasmids or phages carry the bacterial enterotoxin genes. ►Gram-negative/positive, ►peptidoglycan, ►teichoic acid, ►*Streptococcus*, ►*Staphylococcus*; McCormick JK et al 2001 Annu Rev Microbiol 55:77.

Toxicogenomics: Toxicogenomics applies microarray hybridization techniques for the detection of genes that are turned on or off upon exposure of animals to toxic substances. ►microarray hybridization, ►genetox; Simmons PT, Portier CJ 2002 Carcinogenesis 23:903.

Toxin Targeting: ►toxins, ►magic bullet, ►immunotoxin; Goodsell DS 2001 Stem Cells 19:161.

Toxins: Toxins are organic poisons. A plasmid gene of *E. coli* produces colicins and *Shigella* bacteria may affect sensitive bacteria in several ways. The cholera toxin is produced by the bacterium *Vibrio cholerae* and it interferes with the active transport through membranes thus causing the loss of excessive amounts of fluids and electrolytes in the gastrointestinal system. The *Bordetella pertussis* toxin, pertussin, contributes to high levels of adenylate cyclase and thereby to the symptoms of whooping cough. Bungarotoxin (from *Bungarus multicinctus*) and cobrotoxin (from Formosan cobra) in snake venoms block the acetylcholine receptors (McCann CM et al 2006 Proc Natl Acad Sci USA 103:5149) or interfere with ion channel functions. Bungarotoxin has an LD50 value in mice of 0.15–0.21 $\mu\text{g/g}$. Other bacterial toxins include the tetanus toxin, diphtheria toxin, botulin, etc. The diphtheria toxin (of *Corynebacterium diphtheriae* if it carries a temperate phage with the *tox* gene) is one of the most dreaded human poisons (sensitivity is encoded in human chromosome 5q23) with a minimal lethal dose of 160 $\mu\text{g/kg}$

in guinea pigs. Mice and rats are, however, insensitive to this toxin. It inactivates eukaryotic initiation factor eIF-2 in translation on the ribosomes. The fungus *Amanita phalloides* toxin, amanitin (amatoxin), is a poison of RNA polymerase II. About two dozen cytochalasins are synthesized by different fungi and are composed of substituted hydrogenated isoindole rings fused with a macrocyclic ring (large organic compound). Colchicine is a plant alkaloid poison of the spindle fibers. The seed toxin of the plants *Strophantus* and *Acocanthera* is a blocking agent for membrane transport and is used as a selective agent in mammalian cell cultures. Abrin (from a legume) and ricin (from castor bean seeds) are inhibitors of the attachment of aminoacylated t-RNAs to the ribosomes. The piscine toxin, tetrodotoxin (from *Spherooides rubripes*; LD₅₀ in mice 10 µg/kg), and the dinoflagellate, *Gonyalux* species, saxitoxin (LD₅₀ in mice 3.4–10 µg/kg), locks the sodium ion channels and blocks neurotransmission. The curare toxins were obtained originally as an arrow poison from the bark of the trees *Strychnos* and *Chondodendron*. The sources of other curare toxins, bamboo curare, pot curare, gourd curare, etc., are members of the *Menispermaceae* family and are highly poisonous muscle relaxants. They block the acetylcholine receptors and some ion channels. Some of the curare toxins were used medically for treatment of tetanus shock and in surgery to alleviate muscle rigidity. ▶colicins, ▶amatoxin, ▶diphtheria toxin, ▶cytochalasins, ▶aflatoxins, ▶anthrax, ▶colchicine, ▶abrin, ▶ricin, ▶antibiotics, ▶ion channel, ▶acetylcholine receptors, ▶neurotransmitters, ▶LD₅₀, ▶laboratory safety; Schiavo G, van der Goot G 2001 Nature Rev Mol Cell Biol 2:530; Nesioy D et al 2004 Nature [Lond] 429:429; <http://www.epa.gov/iris>.

Toxmap: A geographic information system which provides facts of toxic substances released to the environment by the major manufacturing industries based on government mandated reports: <http://toxmap.nlm.nih.gov/toxmap/main/index.jsp>.

Toxoid: An inactivated bacterial toxin, which may still incite the formation of antitoxins and retain antigenicity.

Toxoplasmosis: Opportunistic infection of about 25% of the human populations by *Toxoplasma* protozoa reducing nerve connections. It is frequently lethal in AIDS and other immune-compromised people. Meiotic recombination among different strains may greatly enhance their virulence. The high virulence of the parasite *Toxoplasma gondii* is due to a secreted serine-threonine kinases (ROP) encoded in chromosome VIIa (Taylor S et al 2006 Science 314:1776; Saeij JPJ 2006 Science 314:1780).

▶AIDS, ▶apicoplast; Grigg ME et al 2001 Science 294:161; Su C et al 2003 Science 299:414.

TP53 (tumor protein): TP53 is now called p53, a tumor suppressor. ▶p53

TPA: A phorbol ester (12-o-tetradecanoyl phorbol 13-acetate) that promotes neoplastic growth after induction has taken place. ▶carcinogens, ▶cancer, ▶phorbol esters

TPA: An inducer protein; a mitogen activating protein kinase C. ▶protein kinases

TPA (Third Party Annotation Sequence Database): An annotation for a sequence that the submitter derived from GenBank primary data: <http://www.ncbi.nlm.nih.gov/Genbank/TP.html>; http://www.ebi.ac.uk/embl/Submission/align_top.html.

TPEA (3' end amplification) PCR: TPEA PCR permits the detection of mRNA at the single cell level (Dixon AK et al 1998 Nucleic Acids Res 29:4426; Subkhankulova T, Livesey FJ 2006 Genome Biol 7: R18). ▶PCR, ▶mRNA

TPK1, TPK2, TPK3: Catalytic subunits of A-kinase. ▶protein kinases

TPM: ▶two-phase mutation model

TPN: TPN is a triphosphopyridine nucleotide; TPNH is the reduced form. They are synonymous with the analogs α-NADP and α-NADPH, respectively. Many enzymatic reactions require β-NADP and β-NADPH (nicotinamide adenine dinucleotide phosphates). ▶NAD, ▶NADP⁺

TPO: TPO modulates megakaryocyte differentiation along with EPO and various cytokines. ▶EPO

TPR: ▶tetratric sequences

TPX2: A microtubule-associated protein. It is required for spindle assembly. Binding to importin α inactivates it but RAN•GTP reverses the binding. ▶microtubule, ▶importin, ▶RAN, ▶spindle; Wittmann T et al 2000 J Cell Biol 149:1405; Gruss OJ et al 2001 Cell 104:83.

T_R: A regulatory T cell. ▶T cells

TR3: ▶nur77

tra (*transformer*): A gene (chromosomal location 3–45) of *Drosophila* that controls sterile male development in XX flies; XY *tra/tra* males are, however, normal males. *tra* acts in cooperation with *tra2* (2–70). Tra and Tra2 proteins mediate sex-specific processing pre-mRNAs of *dsx* (*doublesex*, 3–48.1) and *fru* (*fruitless*, 3–62.0). The transcripts occur in both sexes but are processed differently. In the male germline, Tra2 is required for normal spermatogenesis. Tra2 also

mediates the sex-specific processing of *exu* (*exuperantia*, 2–93) and *att* (*alternative-testes-transcript*, chromosome 3 at 92E3–92E4). The prokaryotic *tra* genes in conjugative plasmids control the conjugal transfer of DNA. ▶sex determination, ▶tra genes

tra Genes: (more than 17) mediate the conjugal transfer of the F and other conjugative plasmids. ▶tra, ▶conjugation, ▶ori_T, ▶relaxosome, ▶plasmids

Trabant: A terminal chromosomal appendage (see Fig. T76). ▶satellited chromosome

Figure T76. Trabant

Trace Elements: Trace elements are only required in minute amounts.

Tracer: A (radioactively) labeled molecule that permits the identification of the fate of the molecules into which it has been incorporated. ▶isotopes

Trachea: The duct leading from the throat (larynx) to the lungs of animals or the duct system of insects through which air is distributed into the tissues. ▶FGF

Tracheid: A long, lignified xylem cell specialized for transport and support in plants.

Trachophyte: A vascular plant endowed with xylem, phloem, and (pro)cambium in-between. ▶xylem, ▶phloem, ▶cambium

Tracking: A mechanism to ensure that transposition occurs between two appropriate *res* (recombination sites). Experimental proofs for successful tracking (reporter rings) are not unequivocal. ▶reporter ring

Tracking Dyes: In electrophoresis, loading buffers permit the visualization of the front migration toward the anode. Bromophenol blue in 0.5 × TBE buffer moves at the same rate as double-stranded linear DNA of 300 bp length. Xylene cyanol FF moves along with 4 kb linear double-strand DNA. ▶electrophoresis, ▶electrophoresis buffers

Tradescantia Species: The *Tradescantia* species occur in the polyploidy range of 2x to 12x. The plants develop ca. 100 stamen hairs in their flowers (see Fig. T77). Each hair represents a single cell line (see Fig. T78). When plants heterozygous for anthocyanin markers are exposed to mutagen, somatic mutations can be assessed as differently colored cell lines in the large number of flowers that single plants may form. Some

of the species have been favorites for cytologists. ▶bioassays in genetic toxicology, ▶somatic mutation; pictures are the courtesy of A Sparrow, and GP Rédei unpublished.

Figure T77. *Tradescantia* stamens

Figure T78. *Tradescantia* stamen hairs

TRADD (tumor necrosis factor receptor associated death domain): ▶tumor necrosis factor, ▶death domain, ▶apoptosis, ▶TRAF

TRAF: A tumor necrosis factor-associated receptor and a signal transducer for some interleukins. TRAF5 is involved in CD40 and CD27-mediated signaling to lymphocytes. TRAF6 activates IκB kinase through a polyubiquitin chain. ▶TNF, ▶TNFR, ▶CRAF, ▶interleukins, ▶TRADD, ▶IRAK, ▶NF-κB, ▶IκB, ▶ASK1, ▶Toll, ▶MATH, ▶Ire, ▶CD27, ▶CD40, ▶ubiquitin; Tada K et al 2001 J Biol Chem 276:36530; Li X et al 2002 Nature [Lond] 416:345.

Tragedy of the Commons: The title of an article published in 1968 by Garrett Hardin (Science 162:1243) where he called attention to the limitations of the “common”—the earth—and the unlimited use of its resources and “freedom to breed” (overpopulation) which will inevitably lead to tragedy because there are no other solutions than the use of

temperance to avoid the consequences of the inevitable necessity. ▶human population growth, ▶cooperation, ▶prisoner's dilemma

TRAIL (Apo-2L, 3q26.1-q26.2): A tumor necrosis factor related apoptosis-inducing ligand which attaches to the death receptor DR4 and mediates apoptosis. DR4 does not respond to FADD like the Fas, TNFR-1, and DR3 system. It has five receptors. TRAIL also activates NF-κB. The nontoxic TRAIL causes preferential killing of neoplastic cells in animal models, especially in combination with radiation therapy of cancer. It appears, however, that it does not discriminate sufficiently between normal human liver cells and liver cancer cells. ▶apoptosis, ▶CD4, ▶death domain, ▶death receptor, ▶FAS, ▶FADD, ▶TNF, ▶TNFR, ▶TWEAK, ▶NF-κB, ▶imaging; Kontny HU et al 2001 Cell Death Differ 8:506; collection of papers in Vitam Horm 2004 vol 67:1–453.

Trailer Sequence: A trailer sequence follows the termination codon at the 3'-end of the mRNA. It is not translated and yet it may have a regulatory function. ▶polyA mRNA

Training Set: A set of observations used to fit the parameters of the classifier of the set. Such sets are generally used for discriminant analysis or multivariate analysis. ▶discriminant function, ▶multivariate analysis; Tsytkin Y 1971 Adaptation and learning in automatic systems, Academic Press, New York.

Trait: A distinguishable character of an organism that may or may not be inherited.

TRAM (translocating-chain associating membrane proteins): TRAMs are membrane-spanning glycoproteins associated with the nascent peptide chain while the SRP mediates its transfer to the endoplasmic reticulum. ▶SRP, ▶protein targeting, ▶translocons, ▶translocase, ▶signal hypothesis

TRAM: Transverse rectus abdominis muscle.

Tramp: An Apo-3 type TNF/NGF receptor. ▶Apo-3, ▶TNF, ▶NGF

Tramp: A polyadenylation cofactor complex of Trf4p (poly A polymerase)-Mtr4p (RNA helicase)-Air2p (zinc knuckle protein) involved with the 3'-5' exonuclease participating in RNA maturation and quality control (LaCava J et al 2005 Cell 121:713; Wyers F et al 2005 Cell 121:725).

Trance (RANK/ODF/OPGL): A tumor-necrosis factor-related activation-induced cytokine ligand (encoded at 13q14) that regulates T cell-dependent immune reactions and bone differentiation, bone mass, and Ca²⁺ metabolism. High levels of the RANK ligand (RNKL) may lead to bone breakdown (osteoporosis),

and estrogen treatment reduces bone loss. The RANKL cytokine triggers migration of human epithelial cancer cells and melanoma cells and leads to metastasis of cancer where RANK is expressed. Cancer metastasis to bones can be blocked using osteoprotegerin but not to other organs (Jones DH et al 2006 Nature [Lond] 440:692). Osteoprotegerin is a TGF-family osteoblast-secreted decoy receptor binding to osteoclasts; it inhibits their maturation. ▶TNF, ▶osteoclast, ▶osteoblast, ▶osteoporosis; Pearce RN et al 2001 Proc Natl Acad Sci USA 98:11581; Theill LE et al 2002 Annu Rev Immunol 20:795.

Trans: A trans position indicates that two genetic markers are not on the same molecule or not on syntenic parts of the chromatids. ▶cis arrangement, ▶syteny, ▶chromatid

Trans Arrangement of Alleles: The trans arrangement of alleles indicates that they are not in the same chromosome (DNA) strand (they are in repulsion). This is in contrast with the cis arrangement (coupling) where the two alleles are within the same strand. ▶coupling, ▶repulsion, ▶cis

Transacetylase: A protein which transfers an acetyl group from an acetyl coenzyme A (Acetyl-CoA) to another molecule. The third structural gene of the lactose operon (*lacA*) encodes a 275-amino acid polypeptide that forms a dimer of 60 kDa that is a transacetylase. ▶lac operon

Trans-Acting Elements: Proteins that are synthesized anywhere in the genome but which regulate transcription by attachment to specific sites of a gene. ▶cis-acting element

Transactivation Responsive Element (TAR): In the HIV transcript the Tat protein binds to the TAR sequence near the 5'-end. This binding then mediates an increased expression of the viral genes and the synthesis of more mRNA. The Rev protein binds to a specific RNA site and to the rev-responsive element (RRE), and facilitates the export of the unspliced transcript to the cytoplasm where viral structural proteins and enzymes are made. ▶acquired immunodeficiency, ▶VP16, ▶transactivator, ▶VDR

Transactivator: A protein domain attached to a specific inhibitory protein that may prevent blocking of transcription and may increase the transcription of the target gene(s) by several orders of magnitude. ▶transactivation responsive element, ▶Switch-Gene, ▶VP16, ▶p53, ▶tetracycline, ▶STAT, ▶two-hybrid method; Devaux F et al 2001 EMBO Rep 2:493; Lottmann H et al 2001 J Mol Med 79:321.

Transactive Catastrophy: The similar base sequences in different organisms or even within the same genome that may have different functional meanings.

Transaldolase Deficiency (TALDO1, 11p15.5-p15.4, a pseudogene is at 1p34.1-p33): Transaldolase deficiency causes cirrhosis of the liver and infantile hepatosplenomegaly (enlargement of the spleen and liver) and accumulation of metabolites of the pentose phosphate pathway (ribitol, D-arabitol and erythrol) in the urine and blood plasma. Male mice lacking transaldolase (TAL^{-/-}) are sterile because of defective forward motility. TAL^{-/-} spermatozoa show loss of mitochondrial transmembrane potential and mitochondrial membrane integrity because of diminished NADPH, NADH, and GSH (Perl A et al 2006 Proc Natl Acad Sci USA 103:14813). ▶[cirrhosis of the liver](#), ▶[pentose phosphate pathway](#), ▶[GSH](#); Verhoeven NM et al 2001 Am J Hum Genet 68:1086.

Transaminases: ▶[aminotransferases](#)

Transcapsidation (heteroencapsidation): The viral coat protein and the enclosed genetic material are of different origin (wolf in a sheep's skin). ▶[pseudovirus](#); Quasba PK, Aposhian HV 1971 Proc Natl Acad Sci USA 68:2345.

Transchromosomal (transchromosomal, TC): A cell which contains foreign chromosomal segments, e.g., a mouse cell with human chromosomal fragment(s). Human chromosome 21 or its fragments in mouse cells provide means of experimentation with Down's syndrome in mice (O'Doherty A et al 2005 Science 309:2033). ▶[chromosome uptake](#), ▶[somatic cell hybrid](#), ▶[alien addition](#), ▶[alien transfer](#), ▶[alien substitution](#), ▶[microcell](#), ▶[Down's syndrome](#); Tomizuka K et al 2000 Proc Natl Acad Sci USA 97:722.

trans-Cinnamic Acid: *trans*-cinnamic acid is formed from phenylalanine by phenylalanine ammonia-lyase and it is converted to a large number of compounds in plants (see Fig. T79). ▶[chalcones](#)

Figure T79. *trans*-Cinnamic acid

Transcobalamin (TCN1): A ligand and transporter of the B12 vitamin; it is encoded in human chromosome 11q11-q12.

Transcobalamin (TC2): A recessive condition which causes megaloblastic anemia, located at human chromosome 22q11 qter. ▶[megaloblastic anemia](#), ▶[anemia](#)

Transconjugant: The bacterial genetic material was (partly) derived by recombination during conjugation. ▶[conjugation](#)

Transcortin Deficiency (CBG): A dominant, human chromosome 14q31-q32 reduction in a corticosteroid-binding globulin. ▶[corticosteroid](#)

Transcribed spacer: A DNA element between genes that is transcribed but eliminated during the processing of the primary transcript. ▶[primary transcript](#)

Transcript: An RNA copied on DNA and complementary to the template. The average number of transcripts per genes is variable and it has been estimated to range from 0.3 to more than 9,400 copies in single human cells. The ENCODE project found 5.4 transcripts per human gene loci formed by alternative splicing. The low copy transcripts are very difficult to recognize. In the relatively small yeast genome, 606 genes showed no mRNA transcripts and 3,796 (~69%) displayed one or fewer transcripts per cell and only ~0.04% had more than 50 transcripts (Akashi H 2003 Genetics 164:1291). Highly important genes have biased usage of the synonymous codons and an abundance of isoacceptor tRNAs. Natural selection for efficient synthesis appears to favor shorter proteins in yeast but not necessarily in other eukaryotes. ▶[transcription](#), ▶[isoacceptor tRNAs](#), ▶[codon usage](#), ▶[intergenic transcript](#), ▶[transfrags](#), ▶[antisense transcript](#), ▶[ENCODE](#), ▶[alternative splicing](#); Velculescu VE et al 1999 Nature Genet 23:387; ▶[human transcript \[database\]](#)

Transcript Cleavage Factor: The transcript cleavage factor induces cleavage and then the release of the 3'-end of a 1- to 17-nucleotide RNA transcript while the 5'-end is still associated with the polymerase. The process may not terminate transcription and transcription may be reinitiated without a deletion in the transcript. In prokaryotes, *GreA* and *GreB*, in eukaryotes transcription factor TFIIIS carry out such functions. The role of the process may be to remove wrong sequences, facilitating the transition from initiation to the elongation phase and the escape of the polymerase from the promoter complex. ▶[RNA polymerases](#), ▶[promoter](#), ▶[transcription complex](#), ▶[transcription factors](#); Conaway JW et al 1998 Cold Spring Harbor Symp Quant Biol 63:357.

Transcript Elongation: Transcription has four basic phases: 1) promoter binding and activation of the RNA polymerase; 2) RNA chain initiation, followed by escape of polymerase from the TATA site; 3) transcript elongation; 4) termination of transcription and transcript release. The elongation phase in *E. coli* is marked by the release of the σ subunit of the

polymerase, the exit of the polymerase from the promoter, and the tight association between the polymerase, DNA template and the nascent transcript ternary complex. Transcript elongation in eukaryotes is quite similar. The rate of elongation varies because of sites of pause, arrest, and termination. In eukaryotes, in vivo the rate of transcription is ~1,200–2,000 nucleotides/minute but in vitro it is only 100–300/minute. Some of the DNA-binding proteins (such as repressors, CCAAT-binding proteins, etc.), gaps in the DNA, or drugs may interfere with elongation although few generalizations are possible at this time. In some instances, the RNA elongation and DNA replication may conflict. During development a variety of controls regulate transcript elongation. The rapid early embryonal development involves relatively shorter transcripts. The crystal structure and function of the RNA elongation complex of *Thermus thermophilus* bacterium has been elucidated (Vassilyev DG et al 2007 Nature [Lond] 448:157). ▶**promoter**, ▶**transcription factors**, ▶**σ**, ▶**walking**, ▶**transcription rate**, ▶**mediator complex**, ▶**elongator**, ▶**elongin**, ▶**ELL**, ▶**RNA polymerase**, ▶**error in transcription**, ▶**tryptophan operon**, ▶**transcription termination**, ▶**attenuation**, ▶**chromatin remodeling**, ▶**TRAP**, ▶**operon**, ▶**inchworm model**, ▶**DRB**, ▶**NELF**, ▶**TFIIS**, ▶**TEFb**, ▶**leukemias [MLL]**, ▶**Cockayne syndrome**, ▶**von-Hippel-Lindau syndrome**; Weliky Conaway J, Conaway RC 1999 Annu Rev Biochem 68:301; Wind M, Reines D 2000 Bioassays 22:327; Touloukhonov I et al 2001 Science 292:730; Pal M, Luse DS 2003 Proc Natl Acad Sci USA 100:5700; Shilatifard A et al 2003 Annu Rev Biochem 72:693.

Transcript Mapping: RNA transcripts are hybridized with specific DNA probes and subsequently the (not annealed) single strands are digested by S1 nuclease. Thus, the resistant (annealed) fragments represent the homologous tracts and demarcate the transcript. For the process of mapping an entire genome, sequence-tagged sites (STS) of cDNAs are used. By the PCR method, the STS sequences can be amplified and their position can be mapped either by YAC clones or by radiation hybrid panels. Using a high throughput system in yeast, 6.5 million probes of both strands of the DNA were interrogated. On rich media, 85% of the yeast genome is expressed. In addition to the expected transcripts, operon-like transcripts were also found. The intergenic regions did not separate some transcripts of adjacent genes, and different parts of the same gene expressed at different levels. Transcript mapping revealed an unexpectedly complex organization of this relatively simple eukaryotic genome (David L et al 2006 Proc Natl Acad Sci USA 103:5320). ▶**nucleic acid hybridization**, ▶**S1 nuclease**, ▶**STS**, ▶**radiation hybrid**, ▶**YAC**, ▶**PCR**, ▶**differential hybridization mapping**, ▶**transfrag**;

Transcriptase: DNA-dependent RNA polymerase or RNA-dependent DNA polymerase or RNA-dependent RNA polymerase enzyme. ▶**RNA polymerase**, ▶**reverse transcription**

Transcription: The synthesis of RNA complementary to a strand of a DNA molecule. In prokaryotes the majority of the transcriptionally active genes are located in the leading strand of replication and are transcribed in the same direction as the DNA synthesis. In the absence of a functional DNA helicase, genes involved in the replication of the lagging strand are hampered by the transcription complex fork and stalled for many minutes. If, however, the DNA helicase is present the replication fork on the lagging strand can quickly pass the RNA polymerase complex. In prokaryotes, transcription and translation are coupled unlike in eukaryotes where the mRNA must be released through the nuclear pore complex into the cytoplasm. Transcription is most commonly regulated by a variety of proteins (transcription factors). In the red clover necrotic mosaic virus (RCNMV), a subgenomic portion (sgRNA) of one of the two RNA genomes (RNA-1), a 34-base portion of the RNA-2, is required for the transactivation of transcription of sgRNA. In eukaryotes, transcription takes place in higher order transcriptional domains (16 in the mouse cell), which are usually independent from the replicational domains. In yeast, transcription and replication appear independent. Based on 678 loci, the Spearman rank correlation coefficient was found to be 0.45 (Washburn MP et al 2003 Proc Natl Acad Sci USA 100:3107). In *Drosophila*, transcriptional activity is correlated with DNA replication at the early S phase.

Transcription in eukaryotes is regulated by the intragenic pattern of the nucleosomal structure. In order to access the gene by RNA polymerase the nucleosomal arrangement must be loosened at the 5'-end of the gene but nucleosomal assembly is maintained downstream to prevent illegitimate transcription initiation. As transcription proceeds the nucleosomal structure is modified in front of the polymerase and reformed as it passes through a particular region. Histone acetylation at the promoter and other critical regions assures the beginning and continuation (elongation) of transcription. Histone deacetylation is mediated by methylation of histone H3 at lysine 36. H3 methylation at lysine 36 is brought about by protein complex Set2, which interacts with RNA polymerase 2 during elongation but not during transcription initiation. The Rpd3 smaller unit is attracted to H3Lysine36

(H3K36) and is involved in deacetylation of the 3'-coding sequences. The larger unit mainly carries out the deacetylation and suppression of the 5'-end promoter region. The Rpd3S and Set2 have functions similar to Spt in chromatin remodeling and function. The histone variant H2A.Z is localized to the nucleosome-free region ca. 200 bp upstream of the first codon of the promoter of many genes. It assists in chromatin remodeling by SWR1 (Lieb JD, Clarke ND 2005 Cell 123:1187). DNA topoisomerase II β (Topo II β), which breaks double-stranded DNA, is required in a signal-dependent manner for the initiation of transcription. Other essential factors include DNA-binding transcription factors, activating protein 1, DNA-dependent protein kinase 1, Ku86, Ku70, CBP coactivator and Pol II that were also recruited. The PARP-1 co-repressor complex (nucleolin, nucleophosmin, heat-shock protein 70) was rapidly eliminated after induction (Ju B-G et al 2006 Science 312:1798).

Transcription Coactivator: A transcription coactivator activates RNA polymerase II but does not bind to DNA. (See Oswald F et al 2001 Mol Cell Biol 21:7761).

Transcription Cofactor: A transcription cofactor links a transcription factor to the transcription complex without binding directly to the DNA.

Transcription Complex: The TATA box-associated complex has the components TFIIA, TFIIB, TFIID, TFIIE, TFIIIF, TFIIH, TFIIJ, TFIIF, and RNA polymerase II. After the Pol II enzyme moves downstream and away from the preinitiation complex and is phosphorylated by a CTDK and TFIIH kinase

action, it can continue transcription in the absence of other regulatory factors although generally specific transcription factors (transactivators) may boost and regulate its activity (see Fig. T80).

Figure T80. Human TFIIE β c structure as determined by nuclear magnetic resonance analysis. This transcription factor binds to the DNA where the promoter opens up when RNA polymerase II initiates transcription. (From Okuda M et al 2000 EMBO J 19:1346. Courtesy Professor Y. Nishimura.)

Usually, a low level of phosphorylation of the heptapeptide repeats of the C terminus (CTD) of the largest subunit of the RNA polymerase is conducive to attraction to the promoter sequences and to the initiation of transcription. The yeast protein FCP is phosphatase, associated with the RNA polymerase II complex, and it facilitates the association of the polymerase to the preinitiation complex. Some transcription factors also play a role in translation. ►RNA polymerase, ►transcription factors, ►regulation of gene activity, ►SRB, ►TBP, ►snRNA, ►transcription factors, ►open promoter complex, ►Hogness (-Goldberg) box, ►Pribnow box, ►transcription shortening, ►CTD, ►elongation factors, ►TCF, ►nucleic acid chain growth; Wolfberger C 1999 Annu Rev Biophys Biomol Struct 28:29; transcriptional regulatory networks: Lee TI et al 2002 Science 298:799.

Transcription Corepressor: A transcription corepressor represses RNA polymerase II without binding to DNA.

Transcription, Ectopic: ►transcription, ►illegitimate

Transcription Factories: A transcription factory is formed when active genes move to shared nuclear subcompartments for transcription and move apart as

transcription ceases (Osborne CS et al 2004 Nature Genet 36:1065). Regions of different chromosomes may make contact within the nucleus and influence gene regulation (Dillon N 2006 Chromosome Res 14:117). Although the chromosomes have some special territories within the nucleus, the intermingling of territories can be visualized at finer resolution (Branco MR, Pombo A 2006 PLoS Biol 4(5):e138). Although some research has indicated that the nuclear periphery is a repressive compartment, newer work indicates that transcription of the mammalian β major-globin gene (responsible for thalassemia) begins at the periphery and that its transcription increases as it moves toward the interior. The locus control region assists in moving the β -globin gene from the nuclear periphery toward the nuclear interior during the maturation of erythroid cells (see Fig. T81). The DNA-dependent RNA polymerase II becomes hyperphosphorylated as it moves to the interior transcription factory (Ragoczy T et al 2006 Genes Dev 20:1447). In yeast, the *GAL* genes move to the nuclear periphery—near the nuclear pore complex—upon becoming transcriptionally activated by members of the SAGA histone acetyltransferase complex (Sus1, Ada2) (Cabal GG et al 2006 Nature [Lond] 441:770). Similarly, the activated subtelomeric hexokinase isoenzyme 1 (*HXK1*) gene moves to the nuclear periphery. This move, controlled by the 3'-untranslated region, is consistent with efficient processing and export of mRNA through the nuclear pore. If the gene was activated by VP16, it moves away from the periphery and induction by galactose abrogated. Accordingly, the nuclear position plays an active role in optimal gene expression (Taddei A et al 2006 Nature [Lond] 441:774). ▶chromosome territories, ▶nucleolus, ▶LCR, ▶RNA polymerase, ▶pol II, ▶SAGA, ▶VP16, ▶hexokinase; Lanctôt C et al 2007 Nature Rev Genet 8:104.

Transcription Factors: A large number of different proteins that bind to either short upstream elements, terminator sequences of the gene, or to the RNA-polymerases and modulate transcription. These specific transcription factors occur in very large numbers and are essential for the function of genes in a particular manner. The $\sim 6,300$ genes of budding yeast are regulated by about 200 transcription factors. Zinc-finger proteins equipped with specific DNA-binding abilities are suitable for engineering functional roles and altered phenotypes such as drug resistance, temperature tolerance, and various developmental pathways (Park K-S et al 2003 Nature Biotechnol 21:1208). The general transcription factors have highly conserved sequences and are interchangeable even among such diverse organisms as mammals, *Drosophila*, yeast, and plants. The TAF proteins, by virtue of their different domains, can modulate the transcription of different genes. Also, the large TAF_{II} protein associated with the TFIID complex, by acetyl-transferase activity, can remodel the chromatin structure and using its amino-terminal kinase activity can transphosphorylate TFIIF and thus modulate transcription of protein genes in two different ways. TFIIB is also capable of self-acetylation as a means of regulating transcription (Choi CH et al 2003 Nature [Lond] 424:965). The specific transcription factors may form a large combinatorial network with various promoter elements.

The transcription factors for RNA polymerase I, transcribing ribosomal RNA genes, show a relatively simple organization (see Fig. T82).

Figure T82. Some transcription factors of RNA polymerase I

The UBF (upstream binding factor) binds upstream in the promoter and regulates transcription by acting as an assembly factor for the transcription complex. TIF-1 or its vertebrate homolog SL1 is required for the attachment of Pol I to the promoter and the accessory proteins A and B assist in the transcription.

The tRNAs, 5S rRNAs and some other small RNAs are transcribed by RNA polymerase III (Pol III). This enzyme has a requirement for protein factor TFIIB and in case of transcribing the 5S rRNA it also requires TFIIIA and TFIIC for the assembly of the transcription complex. Proteins TFIIIA and C, however, are detached after TFIIB binds and only the latter stays on the DNA when Pol III lands and the

transcription begins. TFIIB is not required for the transcription of the tRNAs. The Pol III transcription units also have internal control regions A (box 5'-TG GCNNAGTGG-3') and B (box 5'-GGTCGANN-3') or similar sequences. The U6 snRNA gene of yeast has an elaborate promoter (TATA box, downstream T₇ tract, upstream segment) in the non-transcribed strand. It provides a scaffold for the recruitment for the RNA polymerase III but it is deficient at a subsequent step of promoter opening by TFIIB. It is thus a rare type of single-strand promoter (Schröder O et al 2003 Proc Natl Acad Sci USA 100:934).

The transcription factors required for RNA polymerase II (Pol II), which transcribe protein-coding genes form the most elaborate complex.

The general transcription complex is initiated by binding the TBP (TATA-box-binding protein) subunit of general transcription factor TFIID to the TATA box of eukaryotes (Hogness box) (see Fig. T83). The TFIID complex exists in different forms (α and β) depending on its association with the TAF_{II}-30 protein (in β) or its absence (in α). The TATA box is present in upstream region genes, coding for protein and transcribed by RNA polymerase II. TFIID also attracts TFIIB. TFIID also brings the cleavage-polyadenylation specificity factor (CPSF) to the preinitiation complex and this assists in the formation of the 3'-end of the mRNA. After this, TFIIF, TFIIIE, and TFIIF proteins attach to RNA polymerase II (Pol II) to the TATA box. TFIIF expresses a DNA helicase function (encoded by xeroderma pigmentosum genes XPB and XPD) and a cyclin-dependent protein kinase activity (encoded by CDK7). TFIIF also stimulates transcript elongation by stimulating the phosphorylation of polymerase II and it plays a role in Pol I transcription. In addition, TFIIF stimulates a phosphatase, specific for the largest subunit of the RNA polymerase. The TFIIS protein factor in eukaryotes and *GreA* and *GreB* stimulates transcript cleavage and readthrough. It is a coactivator and regulator of transcription and it binds 3' to the TATA box. The Pol II is inactive at this stage until TFIIF phosphorylates the bound Pol II using ATP as a phosphate donor. The targets of phosphorylation are

several sites near the COOH-end of the largest subunit of pol II. TFIIF also has a helicase, ATPase, and nucleotide excision repair activities. It also mediates promoter melting and promoter clearance. Some genes may be transcribed without the kinase activity of TFIIF yet they need its helicase function. Eukaryotic RNA polymerase II generally contains nine or 12 subunits. The largest subunit is usually about 200 kDa. There are 26 (yeast) to 52 (mammals) repeats (Tyr-Ser-Pro-Thr-Ser-Pro-Ser) close to the carboxyl end. The phosphorylated Pol II then moves out of the complex and can now initiate transcription. The specific transcription factors are operative in special genes and at special tissues and time frames. The transcription factors may also bind a variety of other proteins before or during transcription and thus provide a great variety of fine-tuning of gene expression (Hager GL et al 1992 Curr Opin Genet Dev 12:137). The not absolutely essential TFIID TATA box-binding protein associated factors dTAF_{II} 42 and dTAF_{II} 62 form a heterotetramer resembling the heterotetrameric core of the histone octamer in the nucleosome. The TBP protein subunit of TFIID may also be dispensable in case TAF_{II}30 is present (named TFTC [TBP-free TAF_{II}-containing complex]). The general transcription factors are the basic instruments of transcription initiation but the modulation and regulation of transcription requires a large number of specific factors, activators, coactivators, suppressors and their interactions. Transcription factors with altered specificities can be generated in the laboratory using structure-based design and molecular technology. Besides the general transcription factors that are involved with almost all RNA polymerase II transcribed genes, specific and inducible transcription factors, activators and coactivators as well as chromatin reorganization factors also play an important role. Transcription factors participate in regulatory networks and display altered interactions to varying degrees. A few transcription factors serve as permanent hubs but most act transiently only during certain conditions (Luscombe NM et al 2004 Nature [Lond] 431:308). Quantifying the affinities of molecular interactions is

Figure T83. General transcription complex

difficult because of the large number of variables involved. Also, the interactions are transient and exhibit nanomolar to micromolar affinities, leading to rapid loss of bound material or little bound material. Protein-protein and protein-DNA binding microarrays are especially susceptible to loss because of their stringent wash requirements and may lose weakly bound material. A high-throughput microfluidic platform capable of detecting low-affinity transient binding events on the basis of the mechanically induced trapping of molecular interactions eliminates the off-rate problems facing current array platforms and allows for absolute affinity measurements. Basic helix-loop-helix (bHLH) transcription factors generally bind to a consensus sequence of 5'-CANNTG-3' (N is any nucleotide) called enhancer box or E box, which is the second most conserved motif in higher eukaryotes. Members of the bHLH family show mid- to low nanomolar DNA binding affinities and have off rates above 10^{-2} s^{-1} for their consensus sequences with orders of magnitude higher off rates for non-consensus sequences. The transcription factor binding energy topographies were measured with highly integrated microfluidic devices. The biological function of two yeast transcription factors could be successfully predicted by combining purely in vitro biophysical measurements with informatics knowledge of the genome (Maerkl SJ, Quake SR 2007 Science 315:233).

In the roots of *Arabidopsis*, 80% of the transcription factors seem to be regulated by their upstream noncoding sequences and about one-fourth of the transcription factors are regulated posttranscriptionally by microRNAs or intercellular protein movement (Le J-Y et al 2006 Proc Natl Acad Sci USA 103:6055) (see Fig. T84).

Figure T84. Transcription factor (117) interactions with 72 genes in *Caenorhabditis*. (After Deplancke B et al 2006 Cell 125:1193)

The human genome has ~1,850 transcriptional regulators; that of *Arabidopsis* has 1,533 (~5.9%) whereas *Drosophila*, *Caenorhabditis* and budding

yeast have 635 (4.3%), 669 (3.5%) and 209 (3.5%), respectively. Tissue-specific transcription factors (FOXA2, HNF1A, HNF4A and HNF6) bound to 4,000 orthologous gene pairs in hepatocytes have been purified from human and mouse livers. Despite the conserved function of these factors, 41 to 89% of their binding events seem to be species specific (Odom DT et al 2007 Nature Genet 39:730). These molecules may be further explored for basic research and gene therapy. Viral repressors may prevent the association of RNA polymerase II with the transcriptional preinitiation complex. Using multiphoton microscopy special transcription factor functions can be visualized in vivo (Yao J et al 2006 Nature [Lond] 442:1050). Procedures have been developed for probabilistic predictions for the identities of binding sites and their physical binding energies between transcription factors and DNA (Kinney JB et al 2007 Proc Natl Acad Sci USA 104:501). The nucleosomal structure in eukaryotes must accommodate transcription factors so they can reach the DNA. It seems that spontaneous unwrapping of nucleosomes rather than histone dissociation or chromatin remodeling provides the means for access to the DNA (Bucceri A et al 2006 EMBO J 25:3123).

Transcription Factors, Designed: These include DNA-binding Zinc-finger domains fused to either gene activation or suppression domains. Such constructs may up- or down-regulate the expression of selected targets by affecting chromatin remodeling. ▶ [zinc finger](#), ▶ [polyamide](#), ▶ [fermentation](#); Urnov FD et al 2002 EMBO Rep 3:610; Rebar EJ et al 2002 Nature Med 8:1427; Blancafort P et al 2003 Nature Biotechnol 21:269.

Transcription Factors, Inducible: Inducible transcription factors are proteins that are synthesized within the cell in response to certain agents or metabolites. They bind to short upstream or downstream DNA sequences and affect transcription, frequently by looping the bound DNA back to the promoter area and forming an association with the other protein factors and the general transcription factors. Such transcription factors may be hormones, heat-shock proteins (DNA binding site consensus: CNGAANNTCCNNG), phorbol esters (TGACTCA), serum response elements (CCATATAGG), etc. These protein factors exert their specificity in gene regulation not only by discriminative ability for

individual genes (since their numbers must be lower than that of the genes), but by their modular assembly. ▶ [transcription factors](#), ▶ [hormone response elements](#), ▶ [heat-shock proteins](#), ▶ [HSTF](#), ▶ [regulation of gene activity](#); Mathew A et al 2001 Mol Cell Biol 21:7163; regulated combinations: Setty Y et al 2003 Proc Natl Acad Sci USA 100:7702.

Transcription Factors, Intermediary: Intermediary transcription factors do not associate directly with the promoter but either affect the conformation of the DNA or “adapt” other proteins to the transcription complex. ▶ [open promoter complex](#), ▶ [regulation of gene activity](#); Steinmetz AC et al 2001 Annu Rev Biophys Biomol Struct 30:329.

Transcription Factor Map: The transcription factor map identifies the binding sites of transcription factors in the genome. The binding sites are important in the regulation of development, differentiation, and carcinogenesis. The positions can be revealed by enhancer-binding assays (Hallikas O et al 2006 Cell 124:47) or alternatively a paired-end ditag procedure can be used. The latter procedure found 542 binding sites for p53 (Wee C-L et al 2006 Cell 124:207). ▶ [enhancer](#), ▶ [transcriptome](#), ▶ [p53](#), ▶ [DNA binding protein domains](#), ▶ [paired-end diTAG](#)

Transcription Illegitimate (ectopic transcription): Illegitimate transcription takes place when very low-level transcripts are detected in organs, tissues or developmental stages where these special transcripts are not expected to occur. Usually, nested primers are employed for the amplification. ▶ [housekeeping genes](#), ▶ [tissue-specificity](#), ▶ [nested primer](#); Salbe C et al 2000 Int J Biol Markers 15:41.

Transcription Initiation (transcription start): The DNA forms a transcription bubble when transcription begins. In about 60% of the human genes CpG sequences are located 5' in the early-replicating, highly acetylated gene-rich regions (Cross SH et al 2000 Mamm Genome 11:373). The phage T7 RNA polymerase undergoes a major conformational change at the amino-terminal 300 residues. This then entails the loss of the promoter-binding site and facilitates promoter clearance when the initiation is followed by transcript elongation. The RNA transcript peels off of a seven-base pair heteroduplex and an exit tunnel is created for the enhanced processivity of the elongation complex. ▶ [replication bubble](#), ▶ [promoter clearance](#), ▶ [processivity](#), ▶ [TSS](#); Yin YW, Steitz TA 2002 Science 298:1387; Young BA et al 2002 Cell 109:417; Pokholok DK et al 2002 Mol Cell 9:799; <http://elmo.ims.u-tokyo.ac.jp/dbtss>.

Transcription Rate: The transcription rate may vary from gene to gene and site. Based on fluorochrome

labeling of the β -actin RNA and serum induction indicated 1.1 to 1.4 kb per minute. Yeast RNA polymerase II can synthesize 1.2 kb long sequences/min. The single-subunit bacteriophage RNA polymerase can incorporate in vitro 12–24 kb nucleotides/minute. The bacterial enzyme can build in 3–6 kb/min in vivo and 0.6–2 kb/min in vitro. ▶RNA polymerase, ▶transcription factors, ▶transcript elongation, ▶error in transcription; Brem RB et al 2002 Science 296:752.

Transcription Shortening: RNA polymerase II (RNAP II) hydrolyzes the 3' end of the transcript as part of the process of reading through pause signals and also secures fidelity of the transcription. It requires a TFIIS protein.

Transcription Termination in Eukaryotes: The ribosomal gene cluster is generally terminated much beyond the 28S rRNA gene and at about 200 bp upstream from the core promoter of the following pre-rRNA cluster. In mouse, the Pol I termination signal contains a Sal I box (5'-AGGTCGACCAG [T/A][A/T]NTCCG-3') preceded by T-rich clusters. The actual termination is within the T-rich area and it is assisted by the Sal I box and the T-rich sequences around it. In humans, the conserved repeats (5'-GACTTGACCA-3') terminate pre-tRNA transcription. In *Xenopus* (5'-GACTTGC-3'), repeats and T-rich sequences in the spacer region bring about termination. Probably some proteins bind to the Sal I box. Recently, polypeptide chain release factors (RF) have also been identified in eukaryotes. In yeast, the carboxy-terminal domain (CTD) of the DNA-dependent RNA polymerase II (Pol II) contains a consensus sequence YSPTSPS in multiple copies. Different phosphorylation patterns recruit RNA processing factors after phosphorylation of CTD serine 2. These factors are required for both transcription and termination of transcription. Although Pol II proceeds with transcription beyond the polyadenylation signal, the polyadenylation system cleaves the transcript and the RNA is degraded by the Rtt103 complex and the Rat1/Rai 5'→3' exonucleases joined to the 3'-end of the protein genes, ending transcription (Kim M et al 2004 Nature [Lond] 432:517). The termination mechanism in humans is very similar to that in yeast and it occurs co-transcriptionally (CoTC) by an exonuclease called Xrn2 (West S et al 2004 Nature [Lond] 432:522). The termination in this manner is called torpedo model because the transcription is "torpedoed" at the end. The *Drosophila* N-TEF protein releases the Pol II transcript in an ATP-dependent manner. The Reb-1 yeast protein stops the polymerase and mediates the transcript release. The mouse TTF-1 protein, similarly to Reb-1, binds to the DNA and

brings about termination. Thus the termination mechanisms in different species vary substantially.

In case of DNA, template damage during transcription ubiquitylation at the carboxy-terminal repeat domain (CTD) takes place. If the serine 5 residue (involved in chain elongation) and CTD is phosphorylated, ubiquitylation is inhibited (Somesh BP et al 2005 Cell 121:913).

In the mtDNA a 34 kDa protein (mTERM) is bound to a 13-residue sequence embedded in the tRNA^{Leu(UUR)} and the complex is required for termination of transcription. The MAZ protein may regulate the transcription from different promoters in closely spaced genes. The poly(A) signal is required for the termination of transcription but before the actual termination pretermination cleavage of the RNA transcript takes place. Therefore, before Pol II is released from the DNA it must transcribe the pretermination cleavage site and also the poly(A) signal. ▶polyadenylation signal, ▶transcription termination in prokaryotes, ▶mRNA, ▶rho factor; Langst G et al 1998 EMBO J 17:3135; Dye MJ, Proudfoot NJ 2001 Cell 105:669.

Transcription Termination in Prokaryotes: Transcription termination in prokaryotes can be rho-independent (intrinsic terminators exist in the RNA polymerase) and rho-dependent, i.e., the RNA polymerase requires the cofactor rho for termination of transcription. The terminator regions in various systems have similar structures. They consist of palindromic sequences that can fold back into a hairpin. In the rho-independent terminator there are one or more G≡C rich sequences in the stem; at the base of the stem there are about six consecutive U residues. This structure mediates a pause in the movement of the RNA polymerase thus causing dissociation from the DNA template because the ribosyl-U of the transcript can make only weak hydrogen bonds with the deoxyribosyl-A in the DNA. In the rho-dependent termination, rho recognizes 50 to 90 bases before the hairpin facilitates termination. The *E. coli* protein NusA promotes folding of the hairpin and termination. The λ N protein promotes antitermination. Polypeptide release factors (RF) may also be used in both prokaryotes and eukaryotes. On lambda phage templates, the N-terminal of the 109-amino acid Nun protein of phage HK022 blocks transcription by binding to BOXB on the nascent RNA transcript of the pL and pR operons; and the C-terminal domain interacts with the RNA polymerase. If the RNA polymerase ternary complex (at 3'-OH end) cleaves the transcript, transcription may be reinitiated as long the upstream sequences remain firmly aligned with the DNA. The prokaryotic proteins *GreA* and *GreB* and the eukaryotic TFIIS may favor transcript cleavage.

(See Fig. T85, ▶antitermination, ▶lambda phage; Washio T et al 1998 Nucleic Acids Res 26:5456; Gusarov I, Nudler E 2001 Cell 107:437; Unniraman S et al 2000 Nucleic Acids Res 30:675; Kashlev M, Komissarova N 2002 J Biol Chem 277:14501).

Figure T85. Transcription terminator sequences in prokaryotes

Transcription Unit: The DNA sequences between the initiation and termination of transcription of a single or multiple (co-transcribed, multi-cistronic) gene(s).

Transcriptional Activators: Transcriptional activators are proteins that facilitate the activity of DNA-dependent RNA polymerase(s) in prokaryotes and eukaryotes. Transcription activators may have two independent domains: DNA-binding domain and transcriptional activating domain.

These domains may not have to be covalently associated and dimeric association may carry out their function. In the abstract sketch (see Fig. T86), the dimeric activators stimulate transcription by recruiting the components of the transcription complex to the TATA box, even when transcription may be hindered in their absence or in the presence of the monomers. Employing several of the activators in a non-covalently bound bundle may enhance the potency of transcriptional activation. The addition of six or eight extraamino acids to the yeast Gal4 activator has generated artificial activators. The new activators may have higher or more specific activity. Many of the transcriptional activators (Myc, Jun, etc.) are unstable in the cell and are destroyed by calpains, lysosomal proteases and, most commonly, by ubiquitin-mediated proteolysis. Actually, the activation and the ubiquitination domains functionally

overlap. ▶positive control, ▶negative control, ▶transcription factors, ▶POU, ▶DNA binding proteins, ▶catabolite activator, ▶regulation of gene activity, ▶FK506, ▶FKBP12, ▶transcription complex, ▶GCN5, ▶transcription termination, ▶transcriptional modulation, ▶SW, ▶VDRI, ▶suppression, ▶degron, ▶N-degron, ▶N-end rule, ▶ubiquitin, ▶calpain, ▶destruction box, ▶lysosomes, ▶chromatin remodeling, ▶co-activators; Ptashne M, Gann A 1997 Nature (Lond) 386:569; Hermann S et al 2001 J Biol Chem 276:40127; Lu Z et al 2002 Proc Natl Acad Sci USA 99:8591.

Figure T86. Transcriptional activation

Transcriptional Adaptor: A histone acetyltransferase, acylating histone in the chromatin before activation of transcription. The yeast gene *GCN5* affects, specifically, histones 3 and 4. ▶histone, ▶nucleosome, ▶transcription, ▶transcription initiation

Transcriptional Coactivator: ▶TAF_{II}, ▶co-activator, ▶GCN, ▶coactivators

Transcriptional Control: The regulation of protein synthesis at the level of transcription. ▶regulation of gene activity, ▶signal transduction, ▶transcription factors, ▶operon, ▶regulon

Transcriptional Error: When cytosine is deaminated to uracil in the template DNA strand and the error is not repaired, adenine is incorporated in the RNA transcript in place of guanine (to be inserted by the RNA polymerase). This may be translated into a defective or aberrant protein. Such a mutation may take place in nondividing cells. ▶error in translation

Transcriptional Gene Fusion Vector: The transcriptional gene fusion vectors carry transcription-termination codons (stop codons) in front of the promoterless structural gene, so when the structural gene fuses to a host promoter and is thereby expressed (transcribed with the assistance of a host promoter), it will contain only the amino acid sequences specified by the inserted DNA. ▶gene fusion, ▶read-through proteins, ▶translational gene fusion, ▶trapping promoters, see Figs. T87 and T88.

Figure T87. In the transcriptional gene fusion vector the reporter (APH[3']II, or luciferase or GUS) has no promoter and it is fused to the right border of the T-DNA. The reporter gene is expressed only if it integrates behind a plant promoter that can provide the promoter function. In front of the structural gene here, there are four nonsense codons to prevent the fusion of the protein with any plant peptides. Transcriptional fusion vectors are similar in other groups of organisms. For other symbols and abbreviation see translational gene fusion vectors. (Based on oral communications by Dr. Csaba Koncz)

Figure T88. Transcriptional *in vivo* gene fusion of bacterial luciferase genes to a flower-bud-specific promoter of *Arabidopsis*. The highest level of expression is indicated in red (false color). The background is photographically cleared. (From Rédei GP, Koncz C, Langridge WHR, unpublished)

Transcriptional Gene Silencing (TGS): Transcriptional gene silencing is based on mechanisms of methylation of DNA and chromatin remodeling by proteins or

RNA. ►methylation of DNA, ►chromatin remodeling, ►silencer, ►dosage compensation, ►imprinting

Transcriptional Landscape: The pattern of transcriptional control signals and the transcripts generated.

Transcriptional Modulation: In many transcription factors proline- and glutamine-rich activation domains exist and modulating effects are attributed to them. ►transcriptional activators, ►transcription factor, ►transcriptional suppressor, ►WD-40; Rushlow C et al 2001 Genes Dev 15:340.

Transcriptional Noise: The variation in the rate of transcription due to the assembly of the preinitiation complex, TATA box sequence, TATA box-binding proteins, activators, coactivators, regulatory elements, reinitiation of transcription and thus translation. This noise determines the heterogeneity of gene expression in different cells of the organism and contributes to differentiation and phenotypic differences. ►noise; Blake et al 2003 Nature [Lond] 422:633.

Transcriptional Pause: Pause transcriptional.

Transcriptional Priming: Transcriptional priming occurs when multipotential progenitor cells can be induced to develop into different cell types. GATA-2 and PU.1 transcription factors may have antagonistic or cooperative effects in the determination of cell fate. GATA-2 is required for the generation of mast cells but is not required for differentiation of macrophages. The Ets family member PU.1 is necessary for myeloid and lymphoid cells but not for erythroid or

megakaryocyte lineages. In addition, PU.1 directs the differentiation of hematopoietic cells into macrophages. ►GATA, ►PU.1, ►stem cells; Walsh JC et al 2002 *Immunity* 17:665.

Transcriptional Profiling: ►microarray hybridization

Transcriptional Regulation: ►transcription factors, ►regulation of gene activity, ►quelling, ►methylation of DNA, ►co-suppression, ►posttranscriptional gene silencing, ►RNA noncoding; Carlson M 1997 *Annu Rev Cell Dev Biol* 13:1; Vaucheret H, Fagard M 2001 *Trends Genet* 17:29; Myers LC, Kornberg RD 2000 *Annu Rev Biochem* 69:729; Arnosti DN 2003 *Annu Rev Entomol* 48:579; <http://rulai.cshl.edu/TRED>.

Transcriptional Slippage: Transcriptional slippage occurs when the RNA polymerase transcribes longer or shorter RNA sequences than the actual template, either during initiation or the elongation process. Slippage generally occurs when the template has homopolymeric sequences. (See Larsen B et al 2000 *Proc Natl Acad Sci USA* 97:1683).

Transcriptional Start Site: ►TSS, ►transcription initiation

Transcriptional Suppressor: A transcriptional suppressor can tightly bind to the operator or to other upstream elements of the DNA and thus prevent the initiation of transcription by elements (activators) of the transcription complex. Mot1 is an ATP-dependent inhibitor of the TATA box-binding protein and the members of the NOT complex inhibit the transcription machinery by various ways (TBP, TAF, etc.). Heterochromatin protein (HP1) and histone methyl transferase may also repress genes. ►transcriptional activator, ►transcriptional coactivator, ►transcriptional modulation, ►nucleosome, ►mating type determination in yeast, ►silencer, ►MADS box, ►inhibition of transcription; Ma Y et al 2001 *J Biol Chem Online* Sept 27; Hwang K-K et al 2001 *Proc Natl Acad Sci USA* 98:11423.

Transcriptional Synergy: Multiple transcription factors exert greater effect together than the sum of their individual contributions to gene regulation. ►transcription factors; Green MR 2005 *Mol Cell* 28:399.

Transcriptional Targeting: Transcriptional targeting intends to limit the expression of therapeutically used transgenes to specific cells, e.g., tumor cells. This goal is achievable by the use of tissue-specific promoters, e.g., the carcinoembryonic antigen is expressed mainly in colon and liver cells. The α -fetoprotein promoter is specific for hepatocellular carcinoma. The erbB2 promoter is expressed predominantly in breast tumors and the prostate-specific

antigen is active in prostate cancer. Inducible promoters may be protected from a viral enhancer by insulator elements. ►insulator; Brand K 2004, p 531. In: *Gene and Cell Therapy*. Smyth Templeton N (Ed.) Marcel Dekker, New York.

Transcriptional-Coupled Repair: ►DNA repair, ►excision repair, ►colorectal cancer

Transcriptome: The collection of RNAs transcribed from the genome; transcriptomics is the generation and study of the mRNA profile of the cell. In a single human cell about half of all the genes may be expressed and a total of about 25,000 to 30,000 unique genes are expressed in a human body. The total number of transcripts in the different tissue cells of these unique genes was found to be 134,135. Some genes were expressed only at 0.3 copies per cell while others had up to 9,417 transcripts. About 1,000 transcripts were expressed in five copies in all cells. In some cancer cells some transcripts were present in about 10 copies but absent in normal cells. 40 genes were expressed in all types of cancer cells in about three copies, and this was twice the number for normal cells. The length of the transcripts can be determined by the use of GIS (gene identification signature). The 5' and 3' ends (18 nucleotides each) of full-length cDNAs are extracted and concatenated into paired-end ditags (PETs). These are then mapped to genome sequences to tag the ends of every gene and then these signatures indicate the complete transcription units between the end signatures (Ng P et al 2005 *Nature Methods* 2:105).

The majority of yeast genes have two or more *transcription start sites*. The analysis revealed 667 transcription units in the intergenic regions and transcripts derived from antisense strands of 367 known features. It turned out that 348 open reading frames carry start sites in their 3'-halves to generate sense transcripts starting from inside the reading frame. Thus, the budding yeast transcriptome is considerably more complex than previously thought, and it shares many recently revealed characteristics with the transcriptomes of mammals and other higher eukaryotes (Miura F et al 2006 *Proc Natl Acad Sci USA* 103:17846).

►expression profile, ►SAGE, ►MPSS, ►RIDGE, ►GIS, ►Atlas human cDNA, ►non-ribosomal peptides; Velculescu VE et al 1999 *Nature Genet* 23:387; Caron H et al 2001 *Science* 291:1289; Camargo AA et al 2001 *Proc Natl Acad Sci USA* 98:12103; Appendix II-10; Su AI et al 2002 *Proc Natl Acad Sci USA* 99:4465; Bono H, Okazaki Y 2002 *Current Opin Struct Biol* 12:355; Wu LF et al 2002 *Nature Genet* 31:255; autoannotation tool: <http://jbirc.jbic.or.jp/tact/>; plant transcriptome: <http://plantta.tigr.org>.

Transcriptome Map: 2–30 genes occupy a co-regulated domain in the genome and represent 20 to 2,000 kb. The co-regulated expression domains may control metabolic, developmental and organ-specific pathways. They also occupy nuclear sub-compartments, such as the nucleolus where ribosomal genes and proteins congregate. Neighboring genes mediate histone and nucleosome modifications involved in epigenetic changes. The nucleolus contains the ribosomal proteins and RNA. In cancer, neighboring loci can also be activated and this permits the construction of transcriptome correlation maps (Reyal F et al 2005 Cancer Res 65:1376). ▶[chromatin remodeling](#), ▶[chromosome territories](#); Kosak ST, Groudine M 2004 Science 306:644; Stolc V et al 2004 Science 306:655.

Transcripton: A unit of genetic transcription.

Transcriptosome: A complex of RNA processing proteins (capping enzymes, splicing factors, etc.) within the nucleus, associated with the COOH-terminal domain of the large subunit of RNA polymerase II. ▶[RNA polymerase](#), ▶[transcription factors](#), ▶[post-transcriptional processing](#), ▶[capping enzymes](#), ▶[splicing](#); Halle JP 7 Meisterernst M 1996 Trends Genet 12:161.

Transcytosis: Transcytosis is a process by which immunoglobulin (or other molecules) is/are transported within a vesicle from a secreting cell across the epithelial layer to another domain of the plasma membrane and also receptor-mediated processes of the capillary veins, by a type of endocytosis. ▶[endosome](#); McIntosh DP et al 2002 Proc Natl Acad Sci USA 99:1996.

Transdetermination: A particular pathway of differentiation is overruled by genetic regulation thus e.g., at the *Antp* (*Antennapedia* locus, 3–47.5) “gain of function mutants” in *Drosophila* the antenna is transformed into a mesothoracic leg or a wing in the place of an eye, etc. These changes in the developmental pattern may be associated with chromosomal rearrangements. The breakpoints may be within the promoters.

They may be altered as a cause of transcript heterogeneity and alternate splicing of the transcripts.

Transdetermination occurs in plants (snapdragon, *Arabidopsis* and others) by transforming anthers and pistil into petals and by producing sterile full flowers (see Fig. T89). In animals, transdetermination occurs by changing *Drosophila* antennae into legs, etc. Suppression of the Polycomb group of proteins by JNK signaling induces the changes in the imaginal disks of *Drosophila* (Lee N et al 2005 Nature [Lond] 438:234). ▶[morphogenesis](#), ▶[homeotic genes](#), ▶[imaginal disk](#), ▶[polycomb](#), ▶[JNK](#), ▶[stem cells](#),

▶[determination](#); Hadorn E 1978 Sci Am 219:110; Maves L, Schubiger G 1998 Development 125:115; Wei G et al 2000 Stem Cells 18:409; Glotzer M et al 2001 Annu Rev Cell Dev Biol 17:351.

Figure T89. The apical meristem developed into horn- or antler-shape structures rather than into a normal inflorescence (at left) in *Arabidopsis* mutants (Rédei GP, unpublished)

Transdifferentiation: Transdifferentiation is a rare biological phenomenon when one type of differentiated cells is converted into another discrete type. ▶[transdetermination](#), ▶[regeneration](#)

Transdominant Molecules: Transdominant molecules are used to selectively inhibit gene expression, e.g., antisense RNA, decoy RNA, ribozymes, suppressor proteins, single-chain antibodies. ▶[antisense technologies](#), ▶[suppressor RNA](#), ▶[RNAi](#), ▶[suppressor gene](#), ▶[ribozymes](#), ▶[tumor infiltrating lymphocytes](#), ▶[tumor suppressor factors](#), ▶[TNF](#); Kamb A, Teng DH 2000 Curr Opin Mol Ther 2:662.

Transducer Proteins: Transducer proteins respond to effectors to relay information to cytoplasmic components of the excitation path to switch molecules. After the effector is diluted out, the adaptation pathway leads the restoration to the base condition. (See Wang C et al 2001 Nature [Lond] 412:285).

Transducianism: ▶[creationism](#)

Transducin: A G-protein, G_t , involved in transduction of light signals (RAS-related proteins) regulating cyclic GMP phosphodiesterase. It is activated by cholera toxin and inhibited by the pertussis toxin. ▶[G_t protein](#), ▶[cholera toxin](#), ▶[pertussis toxin](#), ▶[transduction](#), ▶[retinal dystrophy](#); Norton AW et al 2000 J Biol Chem 275:38611.

Transducing Phage: ▶[transduction](#)

Transductant: A transduced cell. ▶[transduction](#)

3' Transduction: Through retrotransposition, the 3' flanking sequences of L1 transposons may move to a position downstream to the poly(A) signal of the parental L1 sequence and it is retained there. This may occur in 10 to 20% of the new retrotranspositions. Much less frequently, 5' transduction can also occur in a similar manner. Such events may rearrange exons and regulatory sequences and may lead to the evolution of new genes. ▶LINE, ▶poly(A) signal, ▶exon shuffling; Moran JV et al 1999 Science 283:1465.

Transduction: The transfer of DNA from one cell to another. In human molecular genetics, the transduced gene, or the transgene, is expected to be expressed in the new location. ▶transformation, ▶transfection

Transduction, Abortive: Transduced DNA is not integrated into the bacterial chromosome and it therefore fails to replicate among the bacterial progenies and is diluted out during the subsequent cell divisions. The non-replicating abortively transduced genetic material is transmitted in a unilinear fashion. See Fig. T90, ▶transduction generalized, ▶transduction specialized; Stocker BAD 1956 J Gen Microbiol 15:575.

Figure T90. Abortive transduction

Transduction, Generalized: A phage-mediated transfer of *unspecified* genes among bacteria (lysogenic or non-lysogenic). The virulent phage breaks down the host cell DNA into various size fragments by the process called lysis. The transducing phage coat may then scoop up fragments of the DNA that fit into the capsule (head) that may not contain any phage genetic material. The DNA fragments enclosed in the phage head are picked up at random from the proper

size group of the bacterial DNA without regard to the genes located in the fragments. For productive transduction the transferred fragments must be stably integrated into the chromosome of the recipient bacteria. ▶specialized transduction, ▶transduction abortive, ▶transduction mapping, ▶pac site, ▶marker effect, see Fig. G23 in generalized transduction; Lederberg J et al 1952 Cold Spring Harbor Symp Quant Biol 16:413.

Transduction Mapping: Determines the map position of very closely linked bacterial genes on the basis of co-transduction frequencies; e.g., if the donor DNA is $a^+ b^+$ and the recipient bacterium is $a^- b^-$ then the recombination frequency is $[(a^+ b^-) + (a^- b^+)] / [(a^+ b^-) + (a^- b^+) + (a^+ b^+)]$. ▶transduction generalized [see Fig. G23].

Transduction, Specialized (or restricted): A temperate-phage-mediated transfer of *special* genes between bacteria. Transduction may be mediated in higher eukaryotes by horizontal transmission, transposable and retrotransposable elements. ▶specialized transduction [see Fig. G23], ▶transposable elements; Morse ML 1954 Genetics 39:984.

Transesterification: An esterase enzyme catalyzes a replacement reaction. A nucleophile displaces an alcohol during the hydrolysis of an ester. A similar reaction occurs when, in nucleic acid processing, phosphodiester exchanges take place at the splice junctions of exons and introns. ▶splicing, ▶introns

TRANSFAC: A database for transcription factors and their binding sites. ▶transcription factors; <http://www.gene-regulation.com/>; <http://www.gene-regulation.com/pub/databases.html>.

Transfection: Originally, the term was coined for introduction of viral RNA or DNA into bacterial cells and the subsequent recovery of virus particles. Today, it is used for introduction of foreign DNA into animal cells where the genes may be expressed. The delivery system may be through microinjection, bombardment (gene gun), electroporation, DEAE dextran, calcium phosphate precipitation of the target cell membranes, liposomes, and polyamidoamine dendrimers (highly branched cationic polymers). After delivery, the DNA needs protection from elimination and degradation by nucleases, opsonins, and endocytosis. Nuclear targeting may be facilitated by polyethylene glycol. Nuclear localization signals, combined with peptide nucleic acid, may facilitate homing in on the nucleus. There may be other hurdles to overcome such as cytotoxicity, condensation of the DNA, tissue targeting, etc. ▶transduction, ▶transformation genetic, ▶microinjection, ▶reverse transfection, ▶DEAE dextran, ▶biolistic transformation,

►electroporation, ►liposomes, ►receptor-mediated gene transfer, ►opsonin, ►endocytosis, ►nuclear localization sequences, ►peptide nucleic acid, ►polyethylene glycol; Földes J, Trautner TA 1964 Z Vereb-Lehre 95:57; Lug D, Saltzman WM 2000 Nature Biotechnol 18:33.

Transfectoma: A hybridoma cell producing a specific mouse/human chimeric antibody. ►hybridoma, ►antibody; Sun LK et al 1991 J Immunol 146:199.

Transfer Clockwise/Counterclockwise: The bacterial F plasmid may be integrated in different orientations and at different locations in the bacterial chromosome and thus Hfr strains may be formed that transfer the chromosome either clockwise or counterclockwise during conjugation. ►Hfr, ►conjugation, ►clockwise, ►counterclockwise

Transfer Factors: Bacterial plasmids capable of transferring information from one bacterial cell to another through conjugational mobilization. Some of the factors (e.g., ColE1) may not have genes for transfer yet they may be transferred to other cells by helper function of conjugative plasmids. These transfer factors may contain genes for resistance (transposable elements) and have great medical significance because of the transfer of antibiotic resistance and thus make the defense against pathogenic infection difficult. ►antibiotics, ►transposable elements bacterial, ►colicins, ►resistance transfer factors

Transfer Horizontal: Same as transfer lateral.

Transfer, Lateral: In lateral transfer, genetic information is transmitted by “infection” (horizontally) or by plasmids rather than by sexual means (vertical transfer). This transfer accounts for a great deal of the variation in prokaryotes. Many species of bacteria take up and maintain extracellular DNA, especially under conditions of starvation. In 22 prokaryotic genomes, the average horizontally acquired sequences constitute ~6% of the genome (Dufraigne C et al 2005 Nucleic Acids Res 33(1):e6). *Salmonella* synthesizes a histone-like nucleoid structuring protein (H-NS) that selectively silences horizontally acquired genes, which contain lower GC content than the recipient genome and thereby protects its fitness against potentially less favorable genes (Wiley Navarre W et al 2006 Science 313:236). Mitochondrial and plastid genes can also transmit horizontally during evolution of higher organisms (Rice DW, Palmer JD 2006 BMC Biol 4:31). The fraction of horizontally transferred genes is not equally frequent among and between phylogenetically distant organisms. In Archaea the Pfam family of protein domains may be laterally acquired in >50%, and in three taxonomic ranges of bacteria, the horizontal transfer

was found to be 30–50% when examined at three taxonomic ranges. In Eukarya, it was <10%. In certain gene families the horizontal transfer was more prevalent than in others (Choi IG, Kim S-H 2007 Proc Natl Acad Sci USA 104:4489). ►incongruence, ►lateral transmission; Pfam, Finkel SE, Kolter R 2001 J Bacteriol 183:6288; Koonin EV et al 2001 Annu Rev Microbiol 55:709.

Transfer Line: A polyploid species carrying a relatively short foreign chromosomal segment in its genome. The transfer is generally made either by crossing over between homoeologous chromosomes, in the absence of a gene or chromosome (chromosome 5B in wheat) that would normally prevent homoeologous pairing. It can be obtained also by (X-ray) induced translocation. Construction of such lines may have agronomic importance for introducing disease resistance or any other gene(s) that are not available in the cultivated varieties or their close relatives. ►alien addition, ►chromosome substitution, ►alien substitution, ►homoeologous chromosome; Sears ER 1972 Stadler Symp 4:23.

Transfer RNA (tRNA): Genes coding for tRNAs are clustered in both prokaryotes and eukaryotes. Some of the tRNA genes are located within the spacer regions of the ribosomal gene clusters.

The majority of tRNA genes is clustered as a group in the DNA, and frequently occurs in –two to three copies. In *Drosophila*, 284 tRNA genes have been identified. In humans there are 497 (plus 324 pseudogenes), in *Caenorhabditis* 584 tRNA genes. Some *E. coli* tRNA (86) gene clusters include genes for proteins. The tRNA genes within the cluster are separated by intergenic sequences and are transcribed as long pre-tRNA sequences. The primary transcript is processed at the 5'-end by RNase P and at the 3'-end by RNase D, BN, T, PH, RNase II, and polynucleotide phosphorylase. The pre-tRNA processing also involves joining the fragments after introns are removed by tRNA ligase multifunctional enzymes (Englert M, Beier H 2005 Nucleic Acids Res 33:388). In the *Nanoarchaeum equitans* bacterium, separate sequences code for the 5' and 3' halves of some tRNAs (Randau L et al 2005 Nature [Lond] 433:537). Before the tRNAs are released to the cytoplasm their integrity is ascertained and only the mature and structurally correct molecules are exported in a Ran-guanosine triphosphate dependent manner. Newer information indicates that in yeast tRNA can shuttle between nucleus and cytoplasm (Takano A et al 2005 Science 309:140).

Aminoacylation takes place before export from the nucleus. The tRNAs are small molecules (70–90 nucleotides). They assume a “clover leaf” secondary structure formed by single-stranded loops and

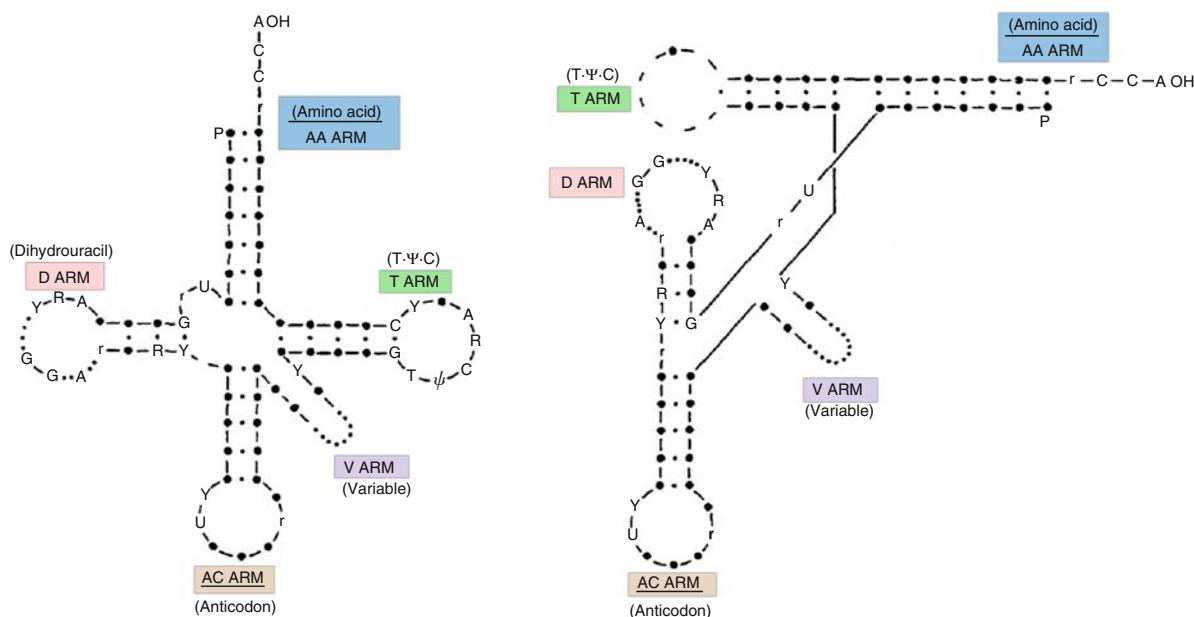

Figure T91. The general structural features of tRNAs. Left: The cloverleaf; Right: The L-shaped tertiary conformation. R stands for purine and Y for pyrimidine bases in all tRNAs; R and Y indicate the occurrence of these bases in many tRNAs; ψ is pseudouridine. (After Kim SH 1976. *Progr. Nucleic Acid Res. Mol. Biol.* 17:181.)

double-stranded sequences. *Caenorhabditis* and some other nematodes have two unusual, yet functional, types of tRNAs: one lacks the T arm and the other lacks the D arm but has a short T arm (Watanabe Y et al 1994 *J Biol Chem* 269:22902).

The functioning tRNAs assume an L-shape configuration (see Fig. T91). After being charged with amino acids (aminoacylation), they haul the amino acids to the ribosomes for translation of the genetic code (protein synthesis). The amino acids are attached to the protruding C-C-A-(OH) amino acid arm and one of the C residues interact directly at the P site with the G2252 and G2253 of the 23S ribosomal subunit of prokaryotes. The 3'-CAA is generally added enzymatically to the tRNA after transcription (Tomita K et al 2004 *Nature [Lond]* 430:700) but some bacterial tRNA genes also encode this sequence (Xiong Y, Steitz TA 2004 *Nature [Lond]* 430:640). The crystal structure and mechanism of function of the CCA-adding RNA polymerase has been elucidated (Tomita K et al 2006 *Nature [Lond]* 443:956). The anticodon loop contains a triplet complementary to the amino acid code word. This anticodon recognizes the code in the mRNA on the surface of the ribosome. The D-arm (dihydrouracil loop) is the recognition site for the aminoacyl-tRNA synthetase enzyme, whereas the T-arm (a thymine-pseudouracil [ψ]-C consensus loop) recognizes the ribosomes. There is also a small variable loop (V arm). Besides the anticodon site, the tRNAs have differences in bases at

other positions too. The tRNA^{Glu} and tRNA^{Gln} can be quite similar yet different as shown in the Figure T92 of the *Staphylococcus aureus* molecule. In eukaryotes, glutamyl-tRNA synthetase directly acylates tRNA^{Gln}. Bacteria and archaea use a tRNA-dependent transamidation process. The first step for Gln-tRNA synthesis is the formation of misacylated Glu-tRNA^{Gln} by a glutamyl-tRNA synthetase, which is used for the formation of Glu-tRNA^{Glu}. This tRNA is converted through transamidation by Glu-tRNA^{Gln}, an amidotransferase. The crystal structure of this bacterial enzyme has been determined (Oshikane H et al 2006 *Science* 312:1950; Nakamura A et al 2006 *Science* 312:1954).

The presence of modified nucleotides is characteristic for tRNAs and they modulate the anticodon domain structure for many tRNA species to accurately translate the genetic code (Yarian C et al 2002 *J Biol Chem* 277:16391). These modifications take place right after transcription or during processing. A small fraction of the base pairs in tRNA are non-conventional, i.e., G-U or A-C and these mispairings are widespread among species and have functional significance, i.e., they enhance aminoacylation and translation (McClain WH 2006 *Proc Natl Acad Sci USA* 103:4570).

The number of tRNAs in prokaryotes is higher than the number of genetic code words (64); in prokaryotes the number of different tRNA molecules may run into hundreds in the different species. In the

Figure T92. Differences in glutamine and glutamic acid tRNAs in *Staphylococcus*. (Modified from references cited)

nematode *Caenorhabditis elegans*, sequencing the entire genome identified 659 tRNA genes and 29 pseudogenes. Since there are only 20 amino acids, of the high number of tRNAs several deliver the same amino acid to the site of translation (isoaccepting tRNA). The amino acid accepting *identity* of transfer RNAs resides within the base sequences and structural features of the tRNAs that are then recognized by aminoacyl tRNA synthetase enzymes. The tRNAs possess dual functions: synthetase and editing, i.e., the removal of the wrong amino acid if attached. The mRNA site recognition is the property of the anticodon. The vast majority of animal and fungal mitochondria synthesize their own tRNAs (about 22). Their anticodon reads the codons by the first two bases and thus do not need isoaccepting tRNAs. Their structure usually lacks the pseudouridine loop, and there are other minor variations. The mitochondria of land plants, algae, *Paramecium*, *Tetrahymena* and *Trypanosomes* partially rely on tRNA import. Organelle tRNAs similarly to those of plants, add post-transcriptionally the 3'-CAA amino acid accepting terminus, in contrast to some cases of *E. coli*. The mitochondrial tRNAs in plants are generally quite variable and show similarities also to the chloroplast tRNAs. The chloroplast tRNAs of higher plants (about 30) may frequently be coded by more than one tract. The universal genetic code requires a minimum of 32 different tRNAs. However, in actuality 26–24 tRNAs (with special wobbles) may suffice for protein synthesis. The mammalian and some fungal mitochondria do not code for all the tRNAs required and import these nuclearly-coded molecules from the cytosol. Many fungi code for 25–27 tRNA genes, however. In *Caenorhabditis*, the tRNA gene number and the number of tRNAs are highly correlated, and the estimated number of tRNA genes is 579 plus 207 tRNA like pseudogenes. Prokaryotes and chloroplasts have a special

tRNA^{F-Met} for the initiation of translation and the same anticodon, CAU may recognize not only the Met codon (AUG) but three other initiator codons as well. Nematodes initiate translation with UUG, which is a leucine codon. tRNAs are used as primers for reverse transcription. During amino acid starvation in bacteria, the guanosine tetraphosphate (ppGpp) is manufactured on the ribosomes with the aid of cognate, uncharged tRNA. Attenuation requires the cooperation of tRNA. In eukaryotes, a unique glutamyl-tRNA reductase mediates the formation 5-amino-levulinic acid, which contributes to the porphyrin ring. ▶tRNA, ▶fMet, ▶rrn genes for tRNAs within ribosomal gene clusters, ▶aminoacyl-tRNA synthase, ▶isoaccepting tRNAs, ▶code genetic, ▶wobble, ▶isoacceptor tRNA, ▶ribosome, ▶mitochondrial genetics, ▶mtDNA, ▶chloroplasts, ▶chloroplast genetics, ▶ribonuclease P, ▶Ran, ▶stringent response, ▶attenuation, ▶porphyrin, ▶modified bases, ▶codon usage, ▶ARAGORN; Giege R et al 1993 Progr Nucleic Acid Res Mol Biol 45:129; Morl M, Marchfelder A 2001 EMBO Rep 2:17; Grosshans H et al 2000 J Struct Biol 129:288; Beuningen PJ, Musier-Forsyth K 1999 Biopolymers 52:1; Intine RV et al 2002 Mol Cell 9:113; tRNA genes: <http://www.tRNA.uni-bayreuth.de>; tRNA functional [initiator, suppressor] classification: <http://tfam.lcb.uu.se/>.

Transfer, Vertical: As per vertical transfer, genetic information is transmitted by sexual means rather than by horizontal, infection type mechanisms.

Transferase Enzymes: Transferase enzymes move a chemical group(s) or molecule(s) from a donor to an acceptor.

Transferrin (TF): A β -globulin (M_r ~75,000–76,000) that transports iron. The encoding gene is located in human chromosome 3q21; the transferrin receptor

(TfR) gene was located nearby. Adenosine ribosylation factors affect the cellular redistribution of transferrin and endocytosis. Transferrin receptor 1 facilitates the infection by New World hemorrhagic viruses (Radoshitzky SR et al 2007 Nature [Lond] 446:92). ▶endocytosis, ▶BLYM, ▶RAC, ▶receptor-mediated gene transfer, ▶hemochromatosis, ▶aceruloplasminemia, ▶atransferrinemia, ▶ferroportin, ▶blood-brain barrier; Aisen P et al 2001 Int J Biochem Cell Biol 33:940.

Transformant: A cell or organism that has been genetically transformed by the integration of exogenous DNA into its genetic material. ▶transformation

Transformation Associated Recombination (TAR): Yeast cells are transformed simultaneously by a YAC vector (TAR) with terminal human genomic repeats, such as Alu and a long piece of human genomic DNA containing interspersed repeats (Alu). Recombination between the YAC and the human genomic DNA within the homologous repeats yields large, stable circular YACs that can be used for mapping or cloning. If the TAR vector contains an *E. coli* F-factor cassette, the vector can be propagated also in bacterial cells. ▶YAC, ▶Alu, ▶F factor, ▶vector cassette; González-Barrera S et al 2002 Genetics 162:603; Kouprina N, Larionov V 2006 Nature Rev Genet 7:805.

Transformation by Protoplast Fusion: ▶protoplast fusion

Transformation, Genetic: Information transfer by naked DNA fragments or plasmid, obviating traditional sexual or asexual processes in prokaryotes and in eukaryotes. Transformation procedures may be transient when the introduced DNA is not being integrated into the genome of the cell. It may also be permanent when the exogenous DNA becomes an integral part of the recipient's genetic material.

Bacterial Transformation. Genetic transformation was discovered in bacteria in the late 1920s. It became a widely used genetic method only in the 1950. Originally, only naked bacterial DNA was used in fragments of 1/200 to 1/500 of the genome. This was provided to *competent* bacterial cells at a concentration of 5–10 µg/mL culture medium. The exogenous DNA can synapse with the bacterial genome and generally only one strand of the transforming DNA is integrated into the recipient, although some bacteria (e.g., *Haemophilus influenzae*) preferentially take up double-stranded DNA from their own species but integrate only one of the strands. Recognition of the homospecific DNA is mediated by uptake signal sequences (USS).

5'-AAGTGC GGT in the plus and 5'-AC CGCACTT in the minus strand. In the completely

sequenced genome of 1,830,137 bp, 1,465 such USS were recognized. *Neisseria gonorrhoeae* also has USS elements (5'-GCCGTCTGAA).

Bacterial transformation generally may not involve an addition, rather a replacement of a part of the DNA of the recipient cell, except when plasmids are used. The non-integrated parts of the donor DNA are degraded and the rest replicates along the genes as a permanent integral part of the bacterial chromosome. The frequency of bacterial transformation may be in the range of 1% or as low as 10^{-3} to 10^{-5} , however, using bacterial protoplasts (spheroplasts) up to 80% transformation is attainable. For bacterial transformation most commonly various genetic vectors are used. Although different empirical procedures are employed in different laboratories, some general features of the methods are obvious. For transformation, either high molecular weight (DNase-free) DNA or plasmids (phage), dissolved in $1 \times \text{SSC}$, is used. Competence in recipient bacteria is induced by CaCl_2 , MnCl_2 , reducing agents and hexamine cobalt chloride or competent cells are purchased in a frozen state from commercial sources. Highly competent cells may yield ca. 10^7 to 10^9 colonies per 1 µg plasmid DNA. The success of transformation is improved by highly nutritious culture media and good aeration. The recognition of transformant cells is greatly facilitated by selectable markers. Transformation of bacteria by electroporation may be extremely efficient (10^{10} transformants/µg DNA). Cultures in mid-log phase are chilled and washed by centrifugation in low-salt buffer. The cells (3×10^{10} /mL) are suspended then in 10% glycerol and can be stored on dry ice or -70°C for up to half year. Thawed aliquots of the cells are mixed with properly prepared donor DNA and exposed to high voltage electric field in small volumes (20–40 µL). Gram-positive bacteria such as *Bacillus subtilis*, is more difficult to transform genetically than the Gram-negative bacteria, e.g., *E. coli*. *B. subtilis* attracted interest for cloning because it is not pathogenic for humans. In the presence of the *B. subtilis* *recE* transformation is facilitated if the cell contains already a plasmid homologous to the vector. Also, spheroplasts in the presence of polyethylene glycol, take up exogenous DNA much easier. Vectors derived from *Staphylococcus aureus* containing tetracycline-(pT127) or chloramphenicol-(pC194) resistance has been successfully used for the development of vectors. *Staphylococcus aureus* is a serious pathogen. Shuttle vectors containing *E. coli* pBR322 and *S. aureus* plasmid elements were also used. Some of the antibiotic resistance genes, e.g., β -lactamase, have very different expression in different species of bacteria. *Streptomyces* were of substantial interest for transformation because of their efficient production of antibiotics. They can be transformed by a sex

plasmid, liposomes and phage vectors. ►competence, ►SSC, ►DNA extraction, ►electroporation, ►vectors, ►cloning vectors, ►liposome, ►β-lactamase, ►antibiotics, ►sex plasmid

Fungal Transformation. Is not entirely different from that in prokaryotes. Transformation of *Neurospora* started already during the early 1970 and caused genetic instabilities in the genome (see RIP). Transformation of budding yeast begun in the late 1970s and became very useful for various types of studies (cloning, YACs, gene replacement, etc.). Yeast cells are grown to about 10^7 density/mL and then suspended in a stabilizing buffer containing 1 M sorbitol. Subsequently the cell wall is removed by digestion with β-glucanase (an enzyme hydrolyzing glucan, the polysaccharide of the cell wall [yeast cellulose]). To the washed spheroplasts in sorbitol, in the presence of CaCl₂ and polyethylene glycol (PEG4000), the donor DNA is added. After about 10 min incubation of the mixture, the cells are gently embedded in 3% agar and layered over a selective medium in a Petri plate. The frequency of transformation depends a great deal on the type of vector used (between 1 to 10^6 colonies per μg DNA). Alternatively — although with lower yield — intact yeast cell have been treated with lithium salts before the DNA and polyethylene glycol is applied. This is followed by selection after spreading the cells onto the surface of selective media. This procedure does not require the production of spheroplasts and agar embedding. Both of these procedures may cause mutations. Similar methods of transformation have been used also in other fungi (*Neurospora*, *Aspergillus*, *Podospora*) and also in green algae. Shuttle vectors were advantageous for the transfer of genes between various fungi and between fungi and bacteria. ►YAC, ►gene replacement, ►episomal vector, ►integrating vector, ►replicating vector, ►centromeric vector, ►shuttle vector

Transformation of Animal Cells. The most commonly used procedures involve precipitation of the donor DNA with calcium phosphate or DEAE-dextran. The precipitated granules may enter animal cells by phagocytosis and up to about 20% of the cells may integrate the donor DNA into the chromosomes. By precipitation, physically unlinked DNA molecules can also be transformed (cotransfected) into the cultured animal cells. The polycation Polybrene (Abbott Laboratories trade name for hexadimethrine bromide) is also used to facilitate the transformation by relatively low molecular weight DNA (plasmid vectors) when some other procedures are not working. Electroporation has also been successfully applied for stable or transient introduction of DNA into the cells. Bacterial (or even plant) protoplasts can also be used to bring about fusion of cell membrane

(in the presence of polyethylene glycol) and this may be followed by transfer of plasmid DNA into animal cell nuclei. This procedure is less efficient than endocytosis mediated by calcium phosphate and the plasmids are frequently integrated in tandem into the chromosome(s) of vertebrates. The exogenous DNA may be introduced also by direct *microinjection* into (pro)nuclei or into embryonic stem cells (ES) and thus generate chimeras (see gene transfer by microinjection). In the latter case the transformed cells can be screened for insert copy number or the insert can be targeted to a specific site by homologous recombination. *Infection* of stem cells, bone marrow, zygotes, early embryos by vectors or by isolated chromosomes is also feasible (►gene transfer by microinjection). Transformation of cultured sperm cells followed by fertilization is another alternative (Kurita K et al 2004 Proc Natl Acad Sci USA 101:1263). Transformation of spermatogonial stem cells of rats with DNA containing geneticin (G418) constructs are capable of self-renewal and retain the ability to colonize recipient testes, remain euploid and thus provide a means for gene targeting and obviate the need for embryonic stem cells (Hamra FK et al 2005 Proc Natl Acad Sci USA 102:17430).

Gene replacement by homologous recombination (►targeting) is also an option. In the latter case sufficient information is required about the needs for critical cis-acting elements. The success of transformation of animal cells varies a great deal according to cell types used. Transformation of vertebrate cells became a very important tool of molecular biology and reversed genetics but unfortunately the transformed cells cannot be regenerated into complete individuals, except when germline or ES cells are transformed. In *Drosophila*, into the cloned P element an isolated gene can be inserted with the aid of genetic engineering and the element may be then microinjected into a young embryo where the DNA can integrate into the chromosome resulting in a stably transformed individual fly. The procedure is particularly effective if the P element vector is equipped also with a selectable marker. In mosquitos microinjection into the egg cells is feasible but was not very effective. A more successful approach was using viral vectors with the vesicular stomatitis virus glycoprotein envelope, which binds to the cell membrane and delivers the foreign DNA. Transgenic rhesus monkeys were produced by injecting pseudotyped replication-defective retroviral vector into the perivitelline space and later fertilized by intracytoplasmic injection of sperm (ICSI) into mature oocytes. ►hybrid dysgenesis, ►ammunition, ►smart ammunition, ►SV40 vectors, ►adenoma, ►Bovine Papilloma Virus vectors, ►retroviral vectors, ►DEAE-dextran, ►Polybrene, ►electroporation, ►polyethylene glycol,

Transformation of Plants. Can be carried out by a variety of procedures. Most extensively used were the techniques of infecting leaf or root explants or protoplasts or seeds by agrobacteria, carrying genetically engineered plasmids.

Practically all dicots can be readily transformed by agrobacteria but some monocots (*Dioscorea*, *Narcissus* and *Asparagus*) could also be transformed. The difficulty with monocot transformation by agrobacteria is apparently caused by the lack of secretion of substances needed for the activation of the virulence gene cascade or monocot cells fail to develop competence in response to infection by *Agrobacterium*. The DNA can be introduced, however by the biolistic methods.

The vector plasmids are either cointegrate or binary. Cointegrate plasmids contain in cis also the virulence genes of the Ti plasmids whereas in the binary vectors the virulence genes are carried by a separate small helper plasmid. Common features of all the vectors are that the genes to be integrated into the plant chromosome are in-between the two 25 bp inverted repeats of the T-DNA. The virulence genes and all other DNA sequences are not integrated into the host genetic material. The left and right border sequences are important for successful transformation but only a few bp of the left border and either none or 1 to 3 bp of the right border are retained in the host (►*Agrobacterium*, ►Ti plasmid). The insertional target is not strictly specified in plants yet a few base similarities are frequently found. It appears that the border repeats scout for appropriate target sites and they are appositioned there. The plasmid virulence genes direct this process also and the bacterial chromosome has also some genes that assist the transformation. The target suffers initial staggered nicks, followed by degradation, and the DNA within the 25 bp borders of the T-DNA is integrated into the chromosome (see Fig. T93). In *Arabidopsis* the histone-2A gene appears to be required for the integration of the T-DNA.

In order to be expressed, the genes within the T-DNA generally carry appropriate (plant compatible) eukaryotic promoters and polyadenylation signals to be expressed in the plant cells. Some vectors may lack promoters and can be expressed only when fused (upon integration) in vivo with plant promoters. These may be translational or transcriptional fusion vectors. The translational fusion vectors lack the

translation initiation methionine codon in order to facilitate the fusion of the structural gene in the T-DNA with some amino acid sequences of the plant host. The purpose of these types of transformation is to study the strength and tissue-specificity of different plant promoters and study the function of fusion proteins. The transcriptional fusion vectors carry one or more translational stop codons (nonsense codons) in the nucleotide tract preceding the ATG (translation initiation codon). Because of this, the structural transgene will be expressed if a genuine plant promoter will drive it and no fusion protein is obtained. These vectors are also shuttle vectors, they can be propagated in agrobacteria and *E. coli*. Being shuttle vectors greatly facilitates various manipulations. The vectors can be replicated in *E. coli* because they have the origin of replication of the pBR322 plasmid and outside the boundaries of the two T-DNA sequences carry genes *oriV* (required for replication) and *oriT* (required for transfer) in *Agrobacterium*. The latter genes were derived from the promiscuous (wide host range) RK plasmid. Aseptically (axenically) grown plant tissues may start the transformation procedure. The vector cassettes generally carry selectable markers, most commonly for resistance against hygromycin B or kanamycin. The gene fusion reporter genes may be (bacterial or firefly) luciferase or GUS (β -glucuronidase) because of the easy monitoring, and the time and space of expression of the fused reporter gene. ►transcriptional gene fusion vector, and ►translational gene fusion vector

Scalpel generally wound the plant explants as they are harvested. Then the tissues dipped into a fresh bacterial suspension (grown to a density of about 10^6 , washed and diluted to about half or less in plant nutrient solution). After the bacteria are blotted off the plant material is incubated for 2 days on the surface of an agar medium in Petri plates (see embryogenesis somatic). Following incubation the bacteria are stopped either by claforan (syn. cefotaxime) or carbenicillin and the plant cells are grown further in media containing also hygromycin or kanamycin (G418) or other selective agent depending of the vector constructs. The regenerated plants may then be grown axenically to maturity in test tubes (in case of *Arabidopsis*) or in soil (in case of larger plants). The transgenes usually segregate as dominant alleles if the plant does not have a corresponding native locus that might mask their expression.

Alternatively, the agrobacterial infection can be applied to presoaked seeds of plants and eventually a small fraction of the embryos developing after meiosis will carry the transgene. Also, seedlings or plants can be infiltrated by agrobacterial suspensions and selection carried out at large scale in soil cultures treated with an appropriate herbicide (Basta) against

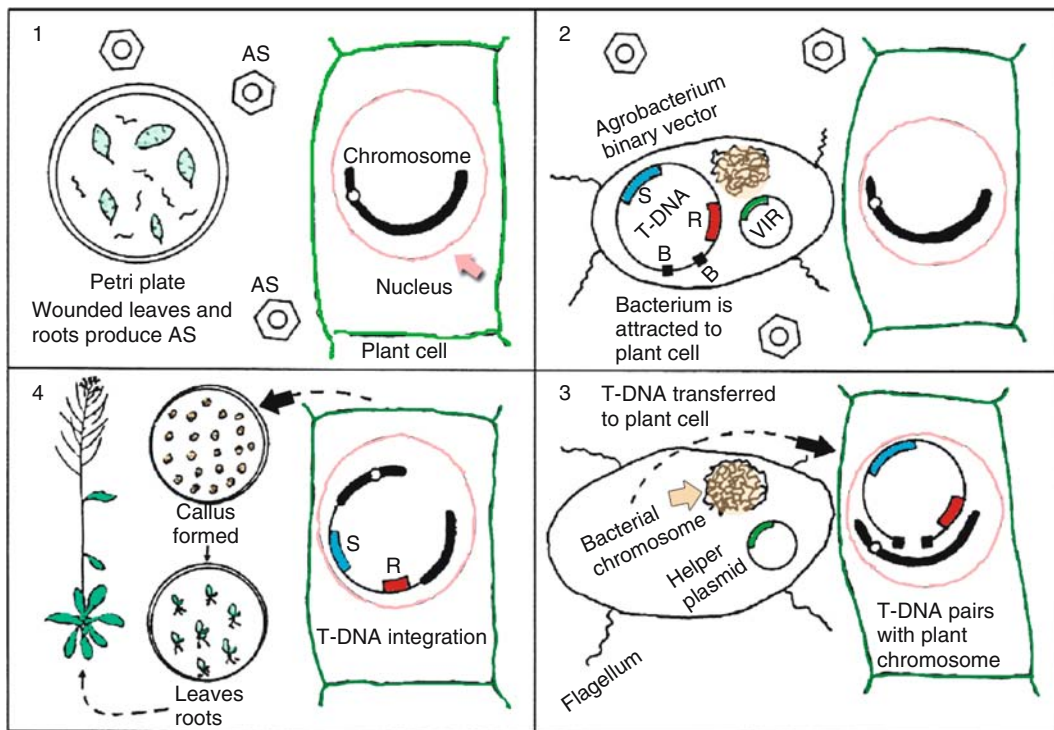

Figure T93. The major steps of transformation of plants by the use of agrobacterial binary vectors. Axenically grown leaves, roots, or stem segments are wounded. The wounding stimulates the production of phenolics such as acetosyringone (AS) and attracts the bacteria carrying the engineered plasmids with selectable markers (S) and a reporter gene (R) placed between the two border sequences (B) of the T-DNA. A small helper plasmid carries the *vir* genes required for transfer and integration of the T-DNA. Two days after infection, the bacterial growth is stopped by antibiotics. The isolated plant organs develop callus, roots, and shoots, and eventually complete plants on the selective media only if the transformation was successful. The transformation is confirmed by the expression of the reporter gene. The transformants produce seed that develops into heterozygous progeny. The antibiotic markers are dominant in the plants

what the vector carries resistance (*in planta* transformation). Plants can be transformed also by electroporation and by biolistic methods. Also cauliflower mosaic virus (CaMV) and geminivirus vectors have been developed but these are not widely used. Generally the vectors carry one desirable gene, for plant breeding purposes it may be desirable the simultaneous transfer of several genes. Assembling in a single transformation vector up to ten genes is feasible. To make such a vector construct the acceptor vector is sequentially altered by the use of two donor vectors and advantage is taken by the Cre/loxP recombination system as well by homing endonucleases (Lin L et al 2003 Proc Natl Acad Sci USA 100:5962). ▶*Agrobacterium*, ▶*floral dip*, ▶*electroporation*, ▶*biolistic transformation*, ▶*microinjection*, ▶*gene transfer by microinjection*, ▶*transformation of organelles*, ▶*genetics of chloroplasts*, ▶*genetics of mitochondria*, ▶*gene trap vectors*, ▶*Cre/loxP*, ▶*homing endonucleases*; Tzfira T et al 2004 Trends Genet 20:375.

Transformation Mapping: A procedure in prokaryotes for determining gene order within the genetic region of integration of the homologous transforming DNA. It can be used as a three-point cross but the additivity of recombination is generally imperfect in transformation. The general principle is outlined at the “bacterial recombination frequency” entry. ▶*bacterial recombination frequency*

Transformation of Organelles: Mitochondria and plastids are also amenable to transformation by exposing protoplasts to appropriate vectors in the presence of polyethylene glycol (PEG) or even more effectively by employing the biolistic procedures. The efficiency of transformation is generally somewhat low. Transformation of organelles is still struggling with methodological difficulties yet it will have great potentials upon further improvements. The number of mitochondria (and plastids) within single cells may run into around hundred or even thousands and that would make possible the amplification of

economically important proteins. Isolated mitochondria can be transformed by conjugation with bacteria. Into a DNA construct the origin of DNA transfer (oriT) is inserted and *E. coli* is transformed first and then through conjugation the construct is mobilized into mitochondria (Yoon YG, Koob MD et al 2005 Nucleic Acids Res 33:(16):2139). Transformation of organelles has the additional safety of containment of the transgenic organisms because mitochondria and plastids are usually not transmitted through the male. The rate of transfer of genes among mitochondria, plastids and nucleus is relatively rare, however it takes place. It may provide a possibility of transferring genes from, e.g., chloroplast to nucleus and the spread the gene in the population by pollination at not negligible rate (10^{-5}). ▶chloroplast genetic, ▶mitochondrial genetics, ▶metabolite engineering, ▶genetic engineering, ▶protein engineering, ▶biolistic transformation, ▶electroporation, ▶transformation, ▶human gene transfer, ▶gene therapy, ▶organelle sequence transfer, ▶Bellophage; Bogorad L 2000 Trends Biotechnol 18:257; Ruf S et al 2001 Nature Biotechnol 19:870.

Transformation, Oncogenic: change to malignant (cancerous) cell growth. Transformed animal cells are anchorage independent and typically free of contact inhibition and may initiate tumors when implanted into immune-compromised animals. Oncogenic transformation results when tumor suppressor genes are inactivated and oncogenes are activated. Spontaneous oncogenic transformation may occur on the same genetic background during repeated passage and proliferation of rodent cells. When these cells are injected into animals they become tumorigenic in the absence of any carcinogen, presumably due to large cell density and selection (Rubin H 2005 Proc Natl Acad Sci USA 102:9276). ▶cancer, ▶carcinogen, ▶gatekeeper, ▶phorbol esters, ▶tumor suppressor, ▶oncogenes; Hunter T 1997 Cell 88:333.

Transformation Rescue: introducing a viable allele or DNA sequences with the aid of transformation compensates for recessive lethal phenotype. By narrowing the transforming DNA to the minimal length that restores a viable phenotype (using restriction enzymes), the site of the damage can be estimated, cloned and sequenced. ▶transformation genetic; de Vries J, Wackernagel W 1998 Mol Gen Genet 257:606.

Transformation, Stable: produces cells which carry the transforming DNA in an integrated form and thus the acquired information is consistently transmitted to the progeny. ▶transformation transient, ▶transformation genetic

Transformation, Transient: The introduced DNA may be expressed only for a limited time (for 1 to 3 days) in the recipient cell because it is not integrated into the host genetic material. Electroporation is most commonly results in this kind of transformation. ▶transformation stable, ▶electroporation

Transformation Vectors: ▶cloning vectors, ▶vectors, ▶transformation genetic

Transformation-Competent Artificial Chromosome Vector (TAC): can carry large (40–80 kb) inserts and can be maintained in *E. coli*, *Agrobacterium tumefaciens* and expressed in plant cells. (See Liu Y-G et al 1999 Proc Natl Acad Sci USA 96:6535).

Transformed Distance (TD): is an UPGMA procedure for species i and j :

$d_{ij} = (d_{ij} - d_{ir} - d_{jr})/2 + c$ where r is a reference species within or outside the group and c is a constant to make d_{ij} positive. This TD formula is unsuitable for the estimation of branch length in evolutionary trees. ▶evolutionary tree, ▶evolutionary distance, ▶UPGMA, ▶Fitch—Margoliash method for TD

Transforming Growth Factor: ▶TGF

Transforming Growth Factor β : A superfamily of proteins that induces the change of undifferentiated tissues into specific types of tissues. TGF- β 1 peptide factor causes reversible arrest in G1 phase of the cell cycle and thus it is considered as a tumor suppressor. TGF- β 1 had been detected in cis position to several genes. These proteins are serine/threonine kinases. ▶activin, ▶bone morphogenetic protein, ▶tumor suppressor, ▶TGF

Transforming Principle: A historical term used in the early bacterial transformation reports when it was not yet proven that DNA is the agent of transformation. (See Alloway JL 1931 J Exptl Med 55:91).

Transformylase: Enzyme that adds a formic acid residue to the methionine-charged fMet tRNA ($tRNA^{fMet}$) in prokaryotes. ▶protein synthesis

TRANSFRAG: Transcribed fragment. On the average number of transfrags in ten human chromosomes were 16,864 with average length of 115 to 78 nucleotides. The average transcripts size varied substantially from 173 to 4650 nucleotides (average 680). On the average of ten chromosomes 31% of the transfrags come from intergenic regions, 26% are intronic and 5% are mRNA. 60.8% of the transcripts are from both genomic strands. Of the 178 cloned transcripts 64% are spliced of 3.2 exons and the average exon length was 238 nucleotides; 26 (14.6%) was spliced from antisense transcripts. Exclusively non-polyadenylated transcript were twice as abundant as the exclusively polyadenylated ones. Many

transcripts (36.9%) were bimorphic, i.e., they had both polyA⁺ and polyA⁻ forms. The polyA⁻ transcripts were mainly intronic. The function of many transcripts still remains unknown in 2005. ▶[transcription](#), ▶[polyadenylation signal](#), ▶[splicing](#), ▶[exon](#), ▶[intron](#), ▶[ENCODE](#); Cheng J et al 2005 Science 308:1149.

Transgene: A gene transferred to a cell or organism by isolated DNA in a vector rather than by sexual means. ▶[transformation genetic](#)

Transgene Mutation Assay: In a transgene mutation assay, a mouse transgenic for a prokaryotic reporter gene is exposed to mutagenic conditions (spontaneous or treated with an agent). The genomic DNA is isolated and rescued in phage lambda vector or used in a plasmid rescue system. The cloning bacteria are then plated and the number of mutant reporter genes compared with all the reporter genes analyzed to provide mutation frequency. Under experimental conditions, spontaneous mutation rates (*lacZ*) were observed within the range about 6 to 80×10^{-6} , depending on the tissues from where the DNA was extracted. Some transgenic lines carry p53 tumor suppressor or the RAS oncogene to test their effects on mutagenesis. Inserted genes of the P450 cytochromes may be helpful for the studies of the metabolism of promutagens and procarcinogens. ▶[host-mediated assays](#), ▶[plasmid rescue](#), ▶[lac operon](#), ▶[β galactosidase](#), ▶[vectors](#), ▶[bioassays in genetic toxicology](#), ▶[mutation detection](#), ▶[promutagen](#), ▶[procarcinogen](#), ▶[P450](#), ▶[p53](#), ▶[RAS](#); Chroust K et al 2001 Mutation Res 498:169; McDiarmid HM et al 2001 Mutation Res 497:39.

Transgenerational Effect: Epimutations transmitted to the progeny. The agouti viable yellow allele *A^{vy}* of mice may be affected in a mosaic pattern by a retrotransposon in the female germline and the alteration is not cleared during subsequent meiosis. Gestating rodent females exposed to antiandrogenic compound (vinclozolin) or an estrogen compound (methoxychlor) (see Fig. T94) reduced spermatogenic cell number and increased infertility in the male offspring and this epigenetic trait reappeared in the

four following generations studied (Anway MD et al 2005 Science 308:1466). ▶[epimutation](#), ▶[directed mutation](#), ▶[sexual selection](#)

Transgenesis: Introducing a gene by genetic transformation. *Conditional transgenesis* introduces the desired gene by *Cre*-mediated recombinase under the control of developmentally-regulated promoter. Germline stem cell transplantation may also lead to transformation. ▶[transformation genetic](#), ▶[Cre](#); Moon AM, Capecchi MR 2000 Nature Genet 26:455; Brinster RL 2002 Science 296:2174.

Transgenic: A transgenic carries gene(s) introduced into a cell or organism by transformation. Transgenic animals can potentially produce therapeutically needed proteins such as human tissue plasminogen activator (tPA) or α_1 -antitrypsin (ATT), human monoclonal antibodies, etc. Transgenic plants may have direct use in agriculture by virtue of their resistance to herbicides, pathogens or even by the production of biodegradable plastics, nutritionally safer fats and carbohydrates, various antigens that may be substituted for the standard type vaccines by eating them. The availability of transgenic crops and farm animals raised concerns by consumers and environmentalists about transfer of herbicide resistance to weeds, to introduce antibiotic resistance genes into the food chains and their potential hazards for fighting microbial infections, affecting the immune system of animals and humans, etc. Although the long-term consequences of the new technologies cannot be precisely assessed yet, there appear more advantages than risks of these new technologies. The wide-scale application of antibiotics in medicine eventually was followed by the appearance of resistance to many antibiotics. It must not be forgotten, however, that antibiotics saved and saving millions of life since the introduction of penicillin after World War II. Also, pharmaceutical research has produced and producing an ever-increasing variety of new antibiotics in order to compete with the evolutionary changes in the microbial world. While the danger of emergence of antibiotic resistant pathogens must not be ignored, the reasonable medical use of these drugs remains

Figure T94. Left: vinclozolin; right: methoxychlor

a necessity. Viral vectors that integrate into the nucleus and can cause unavoidable deleterious modification at the site of insertion most commonly produce transgenic animals. An episomal vector (pEPI) can be delivered with high efficiency to the pig embryo by sperm-mediated gene transfer (SMGT), and the transgene is expressed in all tissues of positive fetuses that were tested, and that is retained as an episome in the course of embryogenesis and fetal development. This procedure successfully produced genetically modified animals (Manzini S et al 2006 *Proc Natl Acad Sci USA* 103:17672). ►[transformation genetic](#), ►[nuclear transplantation](#), ►[antibiotic resistance](#), ►[ANDi](#), ►[paratransgenic](#), ►[bitransgenic regulation](#), ►[genetic engineering](#), ►[gene therapy](#), ►[GMO](#); <http://www.transgenic-animals.com/>.

Transilience, Genetic: Rapid changes in fitness by a multilocus complex in response to changes in the genetic environment. (Templeton AR 1980 *Genetics* 94:1011).

Transin: Cell-secreted metalloproteinase, a homolog of stromelysin. (See Luo D et al 2002 *J Biol Chem* 277:25527).

Transinactivation: ►[co-suppression](#)

Transistor: ►[semiconductor](#)

Transit Amplifying Cell: ►[stem cells](#)

Transit Peptide: Dozen to five dozen amino acid residue leader sequences directing the import of proteins synthesized in the cytosol into mitochondria and chloroplasts. These peptides are generally rich in basic and almost free of acidic amino acids. Serine and threonine are usually very common. The transit peptide recognizes special membrane proteins, but itself is not transferred into the target organelle and it is cut off by a peptidase. The different transit-peptides do not appear to have conserved sequences. The transit peptide is targeted posttranslationally. Some mitochondrial and plastid proteins do not have these cleavable N-terminal sequences. The routing within the target seems to be influenced by the carboxy terminus or inner sequences of the proteins. Mitochondria can import several plastid proteins but the plastids do not import mitochondrial proteins. This mitochondrial import is not physiological because this organelle does not have essential specificity factors (Cleary SP et al 2002 *J Biol Chem* 277:5562). The transit peptide engages several proteins localized in the organelle membranes. Subsequently the protein inside the cell folds with the assistance of chaperonin 60. Some proteins targeted to the endoplasmic reticulum, Golgi membrane, peroxisome, etc., may carry the transit peptide at the C-end. ►[signal peptide](#), ►[chaperones](#); Jean-Benoît P et al 2000 *Plant Cell* 12:319.

Transition Matrix: The conditions of probabilities for a certain type of amino acid substitution during an evolutionary period.

Transition Mismatch: In transition mismatch, purine mispairs with a wrong pyrimidine. ►[transversion mismatch](#), ►[mismatch](#), ►[transition mutation](#)

Transition Mutation: In transition mutation, either a pyrimidine is replaced by another pyrimidine, or a purine by another purine in the genetic material leading to mutation. ►[base substitutions](#), ►[transversion](#); Freese E 1963, p 207. In: *Molecular Genetics* Taylor JH (Ed.) Acad Press, New York.

Transition Proteins: Basic proteins that replace (temporarily) histones during spermiogenesis with protamines. ►[protamine](#), ►[spermiogenesis](#); Finney LA, O'Halloran TV 2003 *Science* 300:931.

Transition State: An unstable (life time $\sim 10^{-13}$ second) intermediate between reactants and products of an enzymatic reaction: REACTANT \rightarrow TRANSITION STATE \rightarrow PRODUCT(S). Factors, which stabilize the transition state relative to the reactant are expected to lower the activation energy. ►[Φ value](#); Komatsuzaki T, Berry RS 2001 *Proc Natl Acad Sci USA* 98:7666.

Transitivity: A bioinformatics concept for sequence analysis of macromolecules. It aids in the identification of distant repeat homologues, for which no alignment has been found, provides confidence about consistently well-aligned regions, and recognizes and reduce the contribution of non-homologous repeats (Szkarczyk R, Heringa J 2004 Bioinformatics 20 (Suppl. 1):1311).

Translation: Converting the information contained in a mRNA nucleotide sequence into amino acid sequences of polypeptides on the ribosomes. mRNA is threaded through a channel wrapping around the 30S subunit of the prokaryotic ribosome and translation initiation, polypeptide chain elongation, and other functions follow (Yosupova GZ et al 2001 Cell 106:233). The translational apparatus of eukaryotes consists of more than 200 macromolecules of varying importance. Some proteins, e.g., bacterial ribosomal proteins S10 and L4, participate both in transcription and translation. ►protein synthesis, ►ribosomal proteins, ►rabbit reticulocyte in vitro translation, ►wheat germ in vitro translation, ►translation nuclear, ►decapping; Sonnenberg N et al (Eds.) 2000 Translational Control of Gene Expression, Cold Spring Harbor Laboratory Press, Cold Spring Harbor, New York.

Translation: The term “translation” is also used for the transfer of basic scientific information into clinical (bench-to-bedside) or other practical applications. ►attrition, ►roadmap

Translation Error: ►error in aminoacylation

Translation Factors: ►translation initiation

Translation Initiation: Translation initiation is usually triggered by growth factors through signaling to the RAS/RAF G proteins and MEK/MAPK proteins. Upon phosphorylation, 4E-BP1 releases the cap-binding protein eIF-4F and the mRNA cap associates with the 40S subunit of the eukaryotic ribosome. The phosphorylation of ribosomal protein S6 by protein kinase p70^{S6k} is also required. Eukaryotic initiation factor eIF-2B is active when it is bound to GTP and ensures the supply of tRNA^{Met}. Insulin and other growth factors keep eIF2B attached to GTP, whereas glycogen-synthase kinase (GSK) inactivates it because GSK inactivates insulin. In prokaryotes, the initiation begins when the ribosomal binding site of the mRNA (including the Shine-Dalgarno sequence and AUG^{fMet} codon) binds to anti-Shine-Dalgarno sequence in the 16S RNA of the 30S ribosomal subunit. The AUG codon thus is directly placed into the P pocket of the ribosome and can interact with the formyl-methionine-charged fMet-tRNA. Before the 30S subunit combines with the 50S subunit, a number

of other interactions also take place. In eukaryotes, the first step of the initiation is the (1) dissociation of the 60S + 40S ribosomal subunit mediated by eIF6 and the attachment of eIF6 to the 60S subunit. Then (2) eIF3 attaches to the 40S subunit, (3) followed by the attachment of eIF1A. Next, (4) eIF2+ GTP combines with tRNA^{Met} and the complex joins the 40S subunit with eIF1A and eIF3 already in place, forming the 43S subunit. (5) The capped mRNA plus elongation initiation factors eIF-4F, eIF-4A, eIF-4B energized by ATP→ADP mediate the attachment of the capped mRNA to the small ribosomal subunit (now 48S pre-initiation complex). (6) While eIF5 and GTPase activating protein (GAP) mediate the release of eIF2•GDP•eIF3 (7) the small subunits scans the mRNA until the AUG^{Met} is located. (8) Capturing the free 60S ribosomal subunit and restoration of the 80S ribosome and beginning of translation follows this event. ►eIF, ►protein synthesis, ►DEAD box, ►cap, ►S6 kinase, ►ribosome, ►Shine-Dalgarno sequence, ►IRES, ►initiator tRNA, ►ribosome scanning, ►PABp, ►mRNA circularization; Gingras A-C et al 1999 Annu Rev Biochem 68:913; Kimball SR 2001 Progr Mol Subcell Biol 26:155; Pestova TV et al 2001 Proc Natl Acad Sci USA 98:7029; Walker M et al 2002 Nucleic Acids Res 30:3181; prokaryotic translation initiation sites detection: <http://tico.bics.de/>.

Translation In Vitro: Translation in vitro used to be accomplished by employing isolated mRNA and other factors required for translation (see wheat germ, rabbit reticulocyte). When the isolated gene is included in an appropriate expression vector, transcription and translation may be obtained in a single step from the plasmid construct. A far more efficiently defined system of in vitro translation employs highly purified and tagged protein factors that permit an efficient purification of the products by affinity chromatography. It may yield 160 µg protein per mL/hr. It can produce modified proteins by incorporating amino acid analogs with the aid of suppressor tRNA. Radioactive tags or non-radioactive fluorescent dyes may label the translation products. ►translation, ►rabbit reticulocyte in vitro translation system, ►wheat germ in vitro translation system, ►suppressor tRNA; Shimizu Y et al 2001 Nature Biotechnol 19:751; Traverso G et al 2003 Nature Biotechnol 21:1093.

Translation, Non-contiguous: In non-contiguous translation, generally the mRNA is translated in a collinear manner into amino acid sequences without skipping any parts of the former. There are few exceptions to this continuity; 50 nucleotides in bacteriophage T4 gene 60 are skipped during translation.

Translation, Nuclear: Translation usually takes place on the ribosomes. In prokaryotes that do not have membrane-enclosed nucleus, transcription and translation are coupled. In eukaryotes intact ribosomes are limited to the cytoplasm and according to the traditional view, translation is limited to the cytoplasmic compartment. Recently, evidence has been accumulating in favor of the notion that even in mammals some translation may take place within the nucleus. The evidence for nuclear translation is based on the observation that in isolated, purified nuclei, fluorescence-labeled proteins were not present outside the nuclei. Electronmicroscopy indicated the colocalization of the nuclear translation sites with the eIF4E polypeptide elongation factor, the ribosomal subunit L7, and a β -subunit of proteasome. The presence of proteasomal activity was surprising inasmuch as that it degrades proteins. It is conceivable that most of the nuclear-translated proteins are degraded normally. Increasing the concentration of ribonucleotides lead to increased protein synthesis in the nucleus, indicating the possibility of coupled transcription and translation in the nucleus. Despite the critical evidence provided, the role and significance of nuclear translation is not entirely clear. ►protein synthesis, ►eIF4, ►proteasome; Iborra FJ et al 2001 Science 293:1139.

Translation Reinitiation: ►reinitiation

Translation Repressor Proteins: Translation repression proteins may be attached to a site near the 5' end of the mRNA and prevent the function of the peptide chain initiation factors. ►protein synthesis, ►eIF-2, ►rabbit reticulocyte, ►aconitase, ►trinucleotide repeats

Translation Termination: Translation termination takes place in the decoding A pocket of the ribosome, where the polypeptide release factors, RF1 recognizing prokaryotic stop codons UAG and UAA, and RF2 specific for UGA and UAA or RF3 without selectivity (and may cause misreading of all three stop signs) release the polypeptide chains. In eukaryotes, the eRF1 termination factor recognizes all three stop codons and eRF1 and eRF3 are interactive. Several other proteins modulate the function of the RFs. RF3 has homology to elongation factors EF-G and EF-Tu. This fact seems to indicate that termination and chain elongation processes bear similarities; in one case the stop codon is read, in the other the sense codons. The Rfs may have additional homology domains, e.g., with the acceptor stem, the anticodon helix, and T stem of tRNAs, called "tRNA mimicry". There is a conserved GGQ (Gly-Gly-Gln) group in eRF1s corresponding to the amino acyl group attached to the CCA-3' end of the tRNA. These homologies may assist their function. The yeast eRF3

is a prion-like element, ψ^+ . Interestingly, the heatshock protein 104, a molecular chaperone can cure the cell from it. After protein synthesis is terminated, the termination complex and the ribosome are recycled. In the 16S rRNA of *E. coli*, mutation at nucleotide position C1054 causes translational suppression. Similarly at the corresponding site in the 18S eukaryotic rRNA, substitutions of A or G resulted in dominant nonsense suppression while the T substitution was a recessive antisuppressor. The deletion of the site was found to have a lethal effect. Although translation termination is mediated at the ribosomes, premature termination may result not just from nonsense codons but also by decay of the mis-spliced transcripts. Bacterial mRNA truncated at the 3'-OH and without a termination codon may stall on the ribosomes. In such cases, the tRNA-like 10Sa RNA transcribed from gene *ssrA* gene of *E. coli* indirectly causes the degradation of the nascent peptide chain. The 10Sa binds to the ribosome and the ANDENYALAA amino acid sequence is added to the C-end of the peptide making it a target for carboxyl-end-specific proteases. Translation termination may regulate gene expression with the aid of some weak internal termination codons, which can be facultatively transpassed. Many human diseases are caused by improper translation termination and modulating the process may have therapeutic potentials. ►translation initiation, ►release factor, ►stop codon, ►sense codon, ►autogenous suppression, ►readthrough, ►recoding, ►EF-G, ►EF-Tu-GTP, ►chaperone, ►prion, ►protein synthesis, ►ribosome, ►phenotypic reversion, ►PABp; Song H et al 2000 Cell 100:311.

Translational Bypassing: Translational bypassing processes two separate open reading frames into one protein. Its mechanism follows. (i) The charged peptidyl-tRNA and mRNA complex arrives to the P site of the ribosome and after dissociation the mRNA slides through the ribosome (take-off). (ii) The peptidyl-tRNA searches the mRNA through the decoding center of the ribosome (scanning). (iii) The peptidyl-tRNA pairs with the appropriate codon after skipping some others (landing). (See Herr AJ et al 2000 Annu Rev Biochem 69:343; Gallant J et al 2003 Proc Natl Acad Sci USA 100:13430).

Translational Control: In translational control, protein synthesis is regulated during the process of translation on the ribosome; e.g., attenuation. The mRNA of some vitamins (B_1 , B_{12}), besides the Shine-Dalgarno sequence, is equipped with a vitamin-binding site. When the vitamin is sensed by the RNA, the Shine-Dalgarno sequence is occluded by a conformational change and thus translation of the vitamin mRNA is suspended in the final outcome reminding to

attenuation (Szostak JW 2002 Nature (Lond) 419:890). ►attenuation, ►termination factors, ►translation termination, ►terminator codons, ►regulation of protein synthesis, ►translational termination, ►suppressor RNA, ►closed-loop model of translation, ►masked RNA, ►ribosomal filter; Gale M Jr et al 2000 Microbiol Mol Biol Revs 64:1092; Johnstone O, Lasko P 2001 Annu Rev Genet 35:365; <http://utther.otago.ac.nz/Transterm.html>.

Translational Coupling: As per translational coupling, when the secondary structure of the mRNA is such that the AUG site or the Shine-Dalgarno sequence is not readily amenable for translation at the first cistron, translation started at the initiator codon of another cistron may open up for translation. Such a situation may occur in phages but rarely also in eukaryotes. (See Herr AJ et al 2000 Annu Rev Biochem 69:343).

Translational Error: ►ambiguity in translation, ►error in aminoacylation

Translational Gene Fusion Vectors: Translation gene fusion vectors carry promoterless, 5'-truncated structural Genes. When the trapped host promoter drives

these, the vectors direct the synthesis of fusion proteins containing amino acid residues coded for by both host and vector DNA sequences. See Fig. T95, ►gene fusion, ►transcriptional gene fusion, ►read-through proteins, ►trapping promoters, ►transformation genetic

Translational Hopping: Translational hopping occurs when a peptidyl-tRNA dissociates from its first codon and then reassociates with another downstream. ►aminoacyl-tRNA synthetase, ►protein synthesis, ►overlapping genes, ►translational frameshift, ►shunting, ►hopping; Herr AJ 2001 J Mol Biol 309:1029.

Translational Recoding (same as ribosomal frame shift): ►overlapping genes

Translational Research: Translational research applies basic research to a patient and determines the outcome of the treatment (Birmingham K 2002 Nature Med 8:647).

Translational Restart: ►reinitiation

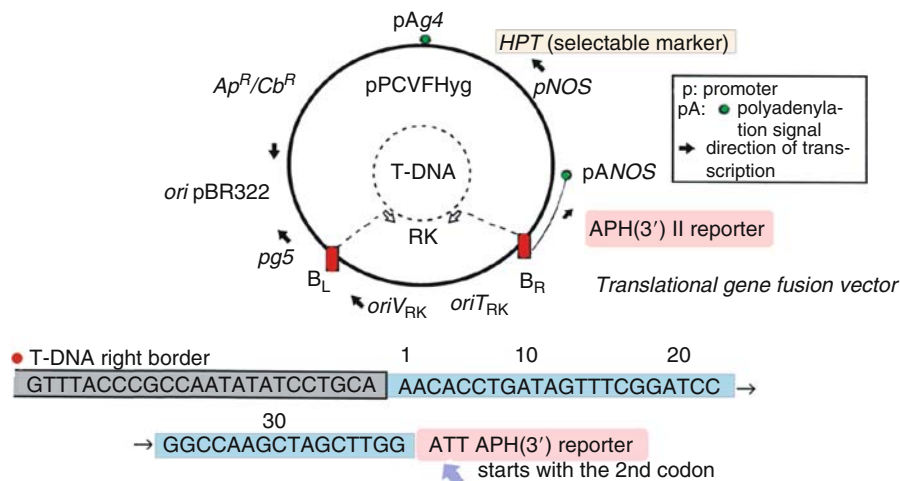

Figure T95. Agrobacterial translational in vivo gene fusion vector for plants. The critical feature is that the reporter gene is fused to the right border sequence of the T-DNA in such a manner that the translation initiator codon (AUG^{Met}) is deleted and the structural gene of the reporter begins with its second codon. It does not have a promoter either. The reporter gene can be expressed only when it is inserted and fused in the correct register into an active plant promoter. Since the AUG codon is missing, there is a good chance that the reporter protein will be fused with some plant (poly-) peptides. The use of such a vector permits an analysis of the expression of various fusion proteins on the reporter. Besides the structure, shown in detail at the lower part of the diagram, the transformation cassette contains selectable markers (e.g., HPT, permitting selective isolation of transformant on hygromycin media), ampicillin (Ap^R) and carbencillin (Cb^R) resistance for selectability in bacteria and also the replicational origin of the *E. coli* plasmid pBR322. Outside the boundaries of the T-DNA, there are genes for both vegetative (oriV) and conjugational transfer (oriT) derived from the multiple-host range RK plasmid. Only the genes between two border sequences (B_L and B_R) are inserted into the plant genome. The basic principle of this diagram has been exploited in designing vectors for other organisms. (After oral communication by Dr. Csaba Koncz.)

Translational Selection: Optimized codon usage. ▶ [codon usage](#); selection of best codons in DNA sequence: <http://genomes.urv.es/OPTIMIZER/>.

Translational Termination: Translational termination may take place by encountering stop codons, endonucleolytic cleavage, shortening the poly(A) tail, and premature decapping of the mRNA. ▶ [translational control](#)

Translesion Pathway: An SOS repair system of DNA; replication may lead to targeted mutation at the site of mismatches, such as at a thymine dimer, and at bases chemically modified or deleted by mutagens. The repair of the cis-syn cyclobutane dimers is mutational in about 6% of the cases, whereas the pyrimidine 6–4 pyrimidinone adducts are repaired in a mutagenic manner in almost 100%. The Rev proteins of yeast and the UmuC (DNA pol V) protein of *E. coli* are involved with translesion. The Rev polypeptides are subunits of DNA polymerase ζ involved in damage-induced mutagenesis. In humans, DNA polymerase η may protect cells against damage that may lead to skin cancer. In bacteria, DNA polymerases II, IV, and V are involved in translesion (Napolitano R et al 2000 EMBO J 19:6259). In bacteria, LexA represses translesion and RecA induces it. Which polymerase is selected depends on the damaging agent. The repair frequently involves mutation. In yeast, the Rad6 and Rad18 proteins are elevated upon UV irradiation and the *REV3*-encoded polymerase ζ unit and a polymerase η carry out the repair. The products of genes *REV7* and *REV1* are also required. In humans, pol ι and pol κ are additional repair polymerases. Werner syndrome protein (WRN) and the translesion polymerases, Pol μ , Pol κ , and Pol ι interact. In vitro, WRN stimulates the extension activity of these polymerases on lesion-free and lesion-containing DNA templates, and alleviates pausing at stalling lesions but increases mutation (Kamath-Loeb AS et al 2007 Proc Natl Acad Sci USA 104:10394). This replicative bypass requires multiple switching to various repair polymerases but after the bypass is completed the high-fidelity polymerases are restored to the replication primer terminus (Friedberg EC et al 2005 Mol Cell 18:499). ▶ [DNA repair](#), ▶ [DNA polymerases](#), ▶ [Y-family DNA polymerase](#), ▶ [REV](#), ▶ [ultraviolet photoproducts](#), ▶ [UMU](#), ▶ [cis-syn dimer](#), ▶ [pyrimidine-pyrimidinone photoproduct](#), ▶ [somatic hypermutation](#), ▶ [Werner syndrome](#); Livneh Z 2001 J Biol Chem 276:25639; Pham P et al 2001 Proc Natl Acad Sci USA 98:9350; Friedberg EC 2001 Cell 107:9; Rattray AJ, Strathern JN 2003 Annu Rev Genet 37:31; Prakash S et al 2005 Annu Rev Biochem 74:317.

Translin: A protein binding to GCAGA[A/T]C and CCCA[C/G]GAC sequences at the translocation

breakpoint junctions in lymphoid malignancies; it supposedly has a role in the rearrangement of immunoglobulin—T cell receptor. ▶ [immunoglobulins](#), ▶ [T cell](#), ▶ [T cell receptor](#), ▶ [TCR](#), ▶ [lymphoma](#); VanLock MS et al 2001 J Struct Biol 135:58.

Translocation: Translocation transfers codons of the mRNA on the ribosomes as the peptide chain elongates. In general, it also refers to any type of transfer of molecules from one location to another. ▶ [protein synthesis](#)

Translocation, Chromosomal: Segment interchange between two nonhomologous chromosomes (see Fig. T96).

Figure T96. Chromosomal interchange

Broken chromosomes do not stick however to telomeres; the interchange must involve internal regions. Fragments may be inserted in-between two ends of an internal breakpoint, and such an aberration is called *shift*. Translocations are detectable by the light microscope, if the length of a chromosome arm is substantially altered. Translocations are usually reciprocal but during subsequent nuclear divisions one of the participant chromosomes, which carries no essential genes may be lost. Heterozygotes for reciprocal translocations display cross-shaped configuration in meiotic prophase (see Fig. T97).

Figure T97. Pairing of reciprocal translocations. Courtesy of Brinkley BR and Hittelman WN, 1975

Translocations repeatedly occur at the same locations of two non-homologous chromosomes and this may be due to the vicinity of these chromosomal sites in the nuclear architecture rather than to the special nature of the DNA sequences (Roix JJ et al 2003 *Nature Genet* 34:287). Translocation between human chromosomes 11q23 and 22q11 occurs repeatedly at frequencies in the 10^{-4} to 10^{-7} range and the breakpoints are most common within ~ 450 bp palindromic sequence of AT-rich repeats of these two regions (Kato T et al 2006 *Science* 311:971).

Translocation heterozygotes generally display 50% pollen sterility in plants because alternate and adjacent-1 distributions occur at about equal frequency in the absence of crossing over; adjacent-2 distributions, being non-disjunctional, are very rare. Note that inversion heterozygotes may also produce 50% male sterility but this occurs only if recombination within the inverted segment occurs freely (see inversion). In animals, the gametes of translocation heterozygotes may succeed in fertilization but the zygotes or early embryos resulting from such a mating are generally aborted. Translocation homozygosity may not have any phenotypic consequence; however, it has been shown that many types of cancerous growth are associated with translocation breakpoints. Apparently, the DNA rearrangements in the vicinity of the genes interfere with the normal regulation of their activity as a kind of position effect. Translocation breakpoints reduce the frequency of crossing over between the breakpoint and the centromere (*interstitial segment*). Recombination in translocation homozygotes may be normal. Because the reciprocal interchange physically alters the synteny of genes, linkage groups may be reshuffled as a consequence of the exchange. Because translocations partially join two linkage groups, they can be exploited for assigning genes to chromosomes. The number of crosses to localize a gene to a chromosome may thus require fewer crosses. Also, the reduction of recombinations around the breakpoints may call attention to linkage over a somewhat larger chromosomal tract rather than a single marker. Furthermore, the association of certain genes with sterility may also be used as a chromosomal marker for the breakpoints. The sterility marker may not always be very useful because it can be recognized only later during development (after sexual maturity). (See Tennyson RB et al 2002 *Genetics* 160:1363). Continued.

Translocation Complex: The interchanged chromosomes of eukaryotes; members of the group are inherited as a complex that alone contributes viable gametes to the progeny.

Translocation Heterozygote: At least two of the chromosomes of the genome are reciprocally

exchanged (mutually translocated) whereas the corresponding homologous chromosomes are not involved in translocation within the same cell nucleus. ▶translocation chromosomal, ▶genome, ▶homologous chromosomes, see Fig. T98.

According to some estimates, there is an about 0.004 chance that a human baby will carry a translocation. Many types of tumors carry translocations and the pattern involved is not a haphazard one. Potential oncogenes (MYC, RAS, SRC) are frequently translocated into the 14q11 region, the location of the T cell receptors (TCR) α and δ . MYC translocated to immunoglobulin genes is common in B cell neoplasia and Burkitt's lymphoma. The chain formation question is intriguing as in how these special translocations are controlled. One interpretation may be that the gene fusions involved may lead to the creation of highly selective combinations to stimulate proliferation. ▶adjacent disjunction, ▶position effect, ▶synteny, ▶multiple translocations, ▶cancer, ▶telomere, ▶B chromosomes, ▶trisomic tertiary, ▶chromosomal rearrangement, ▶oncogenes, ▶Burkitt lymphoma, ▶promoter swapping, ▶unbalanced chromosomal constitution; Generoso WM 1984, p 369. Translocation Ring: Multiple reciprocally translocated chromosomes, after terminalization, are attached end-to-end forming a ring of several chromosomes. (See Fig. T99, ▶ring bivalent, ▶complex heterozygotes, ▶terminalization).

Translocation Test, Heritable: ▶heritable translocation tests under bioassays in genetic toxicology. In some organisms, translocation testers have been developed to expedite linkage analysis. A clear and early marker is translocated to several (tester) chromosomes. Then, the gene to be identified regarding its chromosomal position is crossed with all the translocation testers available. If according to previously obtained information from crosses involving non-translocated chromosomes, the marker in the tester showed independent segregation but was crossed with the translocation testers it is linked to a single specific chromosome, its chromosomal position is revealed. The frequency of translocation may vary a great deal according to the species. In the *Oenothera* plants translocations are widespread and in *Oenothera lamarckiana* all the chromosomes are involved in translocations.

Translocon: The multiprotein complex (SecYp, SecGp, SecE in bacteria, Sec61p, Sbh1p, Ssh1p in yeast,

sec61 α , β , γ in mammals) involved in the transport of proteins through 40–60 Å diameter aqueous pores in membranes, the endoplasmic reticulum. In bacteria,

the DnaK chaperones keep the nascent polypeptide chains in shape until their synthesis is completed. ▶translocase, ▶protein targeting, ▶SRP, ▶TRAM, ▶ABC transporter, ▶ARF, ▶DnaK; Hamman BD et al 1997 Cell 89:535; Heritage D, Wonderlin WF 2001 J Biol Chem 276:22655; cryoelectronmicroscopic revelation of structure of *E. coli* protein-conducting channel bound to translating ribosomes: Mitra K et al 2005 Nature [Lond] 438:318.

Transmembrane Proteins: Transmembrane proteins generally have three main domains; the amino terminus reaches into the cytoplasm where it usually associates with other cytosolic proteins, the hydrophobic domain generally makes seven turns within the cell membrane and the carboxylic end serves as a receptor for extracellular signals (see Fig. T100).

Figure T100. Transmembrane protein

Transmethylation: ►methylation of DNA

Transmission: Transmission indicates whether a particular gene or chromosome survives meiotic or post-meiotic selection and is recovered in the zygotes, embryos, or adults. Apoptotic mechanisms eliminate defective differentiating spermatogonia and elongating spermatids. During oogenesis, apoptosis is less active. This may be the cause of the long-standing knowledge that many (chromosomal) defects are preferentially or to a large extent transmitted through the egg. Transmission is generally reduced if the chromosomes have deficiencies, duplications or structural rearrangements, meiotic drive, maternal-fetal incompatibilities, etc. Monosomes and trisomes also have impaired transmission as well as defective genes. Segregation distorter genes and gametophyte factors may cause reduced transmission. Genetic factors located within the cellular organelles and infectious heredity usually display uniparental (maternal) transmission. *Vertical transmission* indicates transfer by the gametes and *horizontal transmission* means spread of a condition through infectious agents without the involvement of the host genetic system. Horizontal transmission is indicated by sequenced genomes, e.g., in the archaeobacterium *Holobacterium halobium* the dihydrolipoamide dehydrogenase gene displayed 50% homology to that of Gram-positive eubacteria but only 25% to other archaeobacteria. In the *Bacillus subtilis* genome, 10 nucleotide sequences were detected that are of infectious prophage origin.

Transformation by foreign DNA presents the best-documented case for horizontal transfer. Apparent homologies among genes carried by taxonomically

different organisms may be interpreted as convergent evolution. Although horizontal transmission of genes is a fact, during the evolution of higher organisms its role might have been only marginal compared to the Darwinian process (Kurland CG et al 2003 Proc Natl Acad Sci USA 100:9658). The findings of transposable element (SINE) homologies in organisms widely separated taxonomically may be assumed to have origin in retroviral infections. Some of the homologous retrotransposons still carry the characteristic terminal repeats in, e.g., *Vipera ammodytes* and the bovine genome. The transfers might have also been mediated by parasites, such as ticks (*Ixodes*), common to a very wide variety of vertebrates (from reptiles to humans). ►megaspore competition, ►meiotic drive, ►preferential segregation, ►gene conversion, ►certation, ►self-incompatibility, ►infectious heredity, ►transformation, ►transposable elements, ►transposon, ►retroposon, ►retrotransposon, ►intein, ►apoptosis, ►lateral transmission

Transmission Disequilibrium Test (TDT): The TDT is used to ascertain whether a tentative association between two traits is or is not transmitted from the heterozygous parents. This test is not applicable meaningfully to a population where one of the alleles has very high frequency because in such a case the association will appear high, although no causal relationship may be present. The TDT test is not a genetic linkage test. The TDT test can be used to estimate quantitatively the distribution of k offspring carriers of a mutation among r affected progeny by truncated binomials.

$$\text{if } k = r \quad t^k (1 - t^{s-r}) / \{1 - [t^s + (1 - t)^s]\}$$

$$\text{if } 0 < k < r \quad \binom{r}{k} t^k (1 - t)^{r-k} / \{1 - [t^s + (1 - t)^s]\}$$

$$\text{if } k = 0 \quad (1 - t)^r [1 - (1 - t)^{s-r}] / \{1 - [t^s + (1 - t)^s]\}$$

where t = the segregation parameter, s = the size of the sibship.

Segregation distortion can also be determined on the basis of m carriers of the mutation among s genotyped progeny:

$$\text{if parent is typed: } \binom{s}{m} t^m (1 - t)^{s-m}, \text{ if parent is inferred: } \binom{s}{m} t^m (1 - t)^{s-m} / \{1 - [t^s + (1 - t)^s]\}$$

Transmission Genetics: Transmission genetics is actually a misnomer because all genetics deals with inherited (transmitted) properties of organisms and in case there is no transmission there is no genetics. The term has been used to identify those aspects of genetics that deal only with the transmission of genes and chromosomes from parents to offspring involving also the study of segregation, recombination, mutation and other genetic phenomena without the use of biochemical and molecular analyses. It is used in the same sense as classical or Mendelian genetics. ▶ [molecular genetics](#), ▶ [reversed genetics](#)

Transmitochondrial: Cells containing mitochondrial DNA introduced exogenously. The procedure is suitable to produce animal models for human mitochondrial diseases. ▶ [mtDNA](#), ▶ [heteroplasmy](#), ▶ [mitochondrial diseases in humans](#); Hirano M 2001 Proc Natl Acad Sci USA 98:401.

Transmitter-Gated Ion Channel: The transmitter-gated ion channel converts chemical signals, received through neural synaptic gates, to electric signals. The channels in the postsynaptic cells receive the neurotransmitter. The process results in a temporary permeability change and a change in membrane potential, depending on the amount of the neurotransmitter. Subsequently, if the membrane potential is sufficient, voltage-gated cation channels may be opened. ▶ [ion channels](#)

Transmogrification: A complete metamorphosis of living creatures, such as in the case of mythological chimeras, satyrs, mermaids, etc. Genetic engineering and organ transplantation in medicine now bring into reality—in some way—the formerly imaginary beings; animals and plants expressing bacterial genes or vice versa. ▶ [chimera](#), ▶ [homeotic genes](#), ▶ [gene fusion](#), ▶ [allografts](#)

Trans-Morphism: Variations in the low-copy repeats are situated in trans position (repulsion), i.e., one variant in one, the other is in the other homologous chromosome. ▶ [cis-morphism](#)

Transmutation: Changing one species into another (an unproven idea). Also, changing one isotope into another by radioactive decay or changing the atomic number by nuclear bombardment.

Transomic: ▶ [transsomic](#)

Transorientation Hypothesis: The transorientation hypothesis suggests a fourth site (D [decoding]) on the ribosome (besides A, P, and E) and assumes that the EF-G-GTP and tRNA ternary complex rotation (transorientation) moves the tRNA from the D site to the A site during protein synthesis. ▶ [ribosomes](#); Simonson AB, Lake JA 2002 Nature [Lond] 416:281.

Transpeptidation: The transfer of an amino acid from the ribosomal A site to the P site. ▶ [protein synthesis](#), ▶ [aminoacyl-tRNA synthetase](#)

Transpiration: Releasing water by evaporation through the stoma in plants, and through exhalation, through the skin, etc., in animals. ▶ [stoma](#)

Transplacement: Gene replacement with the aid of plasmid vectors. ▶ [gene replacement vector](#), ▶ [localized mutagenesis](#), ▶ [targeting genes](#)

Transplantation: The transfer of tissues or subcellular organelles or other cellular components from one site to another within an organism or between related or unrelated organisms. Transplantation among genetically non-identical organisms may have serious immunological barriers. ▶ [grafting](#), ▶ [grafting in medicine](#), ▶ [graft rejection](#), ▶ [graft-versus-host disease](#), ▶ [stem cells](#)

Transplantation Antigens: Proteins on the cell surface, encoded by the major histocompatibility (MHC) genes; they play a major role in graft (allograft) rejection in mammals. The rejection may depend on the perception of the foreign antigens (tissues) by the lymphoid organs. Transplantation of lost or severely damaged body parts (limbs, face) is technically feasible but the reconstruction surgery—unless from the patient's own body—mandates life-long treatment with immunosuppressors. The French facial tissue transplantation also used twice hematopoietic stem cells from the facial donor tissues in the hope that immune tolerance may develop. Despite these efforts, acute rejection was experienced three weeks after the surgery. Even with the use of all immunosuppressive methods available, rejection may occur within one or two years after the transplantation. These plastic surgeries involve also psychological problems along with the medical ones (Okie S 2006 New Eng J Med 354:889). ▶ [HLA](#), ▶ [mixed lymphocyte reaction](#), ▶ [microcytotoxicity assay](#), ▶ [transplantation](#)

Transplantation In Utero: Postnatal transplantation of foreign tissue generally results in adverse immunological reaction and rejection of the engraftment. This is very serious problem in blood transfusion, grafting, and stem cell therapy. Immature fetuses do not have yet fully developed immune systems. Therefore, attempts have been made to introduce foreign tissue (human hemopoietic stem cells) into developing fetuses at about the first third or even shorter period of pregnancy in the goat (Zeng F et al 2005 DNA Cell Biol 24:403), sheep (Zanjani ED et al 1992 J Clin Invest 89:1178), monkeys (Harrison MR et al 1989 Lancet 2(8677):1425) and other animals. Such transplants were highly successful and various types

of human tissues differentiated and were identified in the animals after two years without rejection. Such a procedure obviates the use of immunosuppressive treatment. By the use of green fluorescent protein markers the right topography of the differentiated tissue could be followed (Zeng F et al 2006 Proc Natl Acad Sci USA 103:7801). ►stem cells, ►hemopoiesis, ►immunosuppression, ►immune tolerance

Transplantation of Organelles: As per transplantation of organelles, nuclei, isolated chromosomes, mitochondria, and plastids can be transferred into other cells by cellular (protoplast) fusion and by microinjection. In case of nuclear transplantation, the resident nucleus is either destroyed (by radiation) or evicted by the use of the fungal toxins, cytochalasins. The enucleated cell is called *cytoplast* and the nucleus surrounded by small amount of cytoplasm is a *karyoplast*. After introduction into the cytoplast of another nucleus by fusion, a *reconstituted cell* is obtained. The individual components are labeled either genetically or by radioactivity or by staining or even mechanically (by 0.5 µm latex beads). The transferred organelles may express their genetic information and can be isolated efficiently and identified if selectable markers (e.g., antibiotic resistance) are used. Defective livers may be repopulated with normal liver cells expressing transgenic BCL-2 because of its protection against apoptosis mediated by FAS. Without BCL-2, the transplanted liver cells do not survive. Such a procedure may eventually become an alternative to liver transplantation. ►cell fusion, ►transformation genetic, ►nuclear transplantation, ►apoptosis, ►paternal leakage, ►rejection; Kagawa Y et al 2001 Adv Drug Deliv Rev 49:107; Kuhholzer B, Prather RS 2000 Proc Soc Exp Biol Med 224:240.

Transplastome: The plastid genome, containing DNA introduced by transformation. ►plastome, ►chloroplasts, ►chloroplast genetics

Transponder (microtransponder): A few hundred micrometer wide silicon chip-based device for memory storage. When prompted by laser light it emits a radio signal that transmits its identification number. In a manner similar to DNA chips, it may assist identification of DNA sequences that are recognized by a probe. ►DNA chips, ►probe

Transport Elements, Constitutive (CTE): CTE permit the transport of spliced and non-spliced RNAs (such as viral RNAs, U snRNAs, tRNAs) although unspliced mRNAs are not exported from the nucleus. ►splicing, ►nuclear pore, ►RNA export, ►RNA transport

Transportan: ►cell-penetrating peptide

Transporters: Permease proteins that assist the transport of various molecules and ions through membranes.

►membranes, ►receptors, ►G-proteins, ►ABC transporters, ►CAT transporters, ►GLAST, ►PROT, ►GLYT, ►rbat/4F2hc, ►ASCT1, ►TAP, ►DNA transport; Sprong H et al 2001 Nature Rev Mol Cell Biol 2:504; Alper SL 2002 Annu Rev Physiol 64:899; <http://plantst.sdsc.edu>; transporter classification: <http://www.tcdb.org/>.

Transportin: A 90 kDa protein, distantly related to importin, which mediates nuclear transport with the M9, 38-amino acid, transport signal by a mechanism different from that of the importin complex. ►importin, ►karyopherin, ►nuclear localization sequences, ►nuclear pore, ►RNA export, ►export adaptor; Lai M-C et al 2001 Proc Natl Acad Sci USA 98:10154.

Transposable Elements: Transposable elements occur in the majority of organisms. Their major characteristic is that they are capable of changing their position within a genome or may move from one genome to another. Transposable elements are classified into two major groups. Class I elements transpose with an RNA intermediate. Class II elements rely on a cut-and-paste mechanism. Elements that lack terminal repeats are unable to transfer horizontally. The estimated rate of transposition is about 10^{-5} to 10^{-4} per element in *Drosophila*. The frequency of transposition may be regulated also by the host genome in lower and higher organisms as well as by methylation of the transposase. Transposable elements can remain silent in the host genomes as of cryptic elements. In such cases, epigenetic mechanisms suppress their activity (Slotkin RK, Martienssen R 2007 Nature Rev Genet 8:272). Also, the various types of elements may have intrinsic differences in mobility. The eukaryotic elements can be either retrotransposons (retrovirus-like) and have long direct terminal repeats (Class I.1) or do not have long terminal repeats (Class I.2), also called retroposons. Both types of Class I elements also possess active or inactive reverse transcriptase. The Class II elements have inverted terminal repeats that code for transposase. Transposition may take place through an RNA intermediate or directly by DNA. Transpositions may take place by homologous recombination between elements located at different map positions in the genome. Close to 50% of the human genome consists of transposons and about 70% of the maize genome is transposable. Transposable elements may have an evolutionary role in the remodeling of the genomes. Transposable elements are transmitted from generation to generation but selection may act against them because insertions may damage the genes; and an equilibrium may generally be reached. The I element of hybrid dysgenesis in *Drosophila*

carries an internal sequence that regulates copy number. After about 10 generation of the inclusion of the first I element, transposition is ‘tamed’, i.e., this internal sequence slows down the movement of the transposon. Elements with regulated transposition rate are successful in invading a population and after a burst their activity is limited and their presence is secured (Le Rouzic A, Capi P 2005 Genetics 169:1033). The strength of selection for host alleles controlling transposition may be estimated according to Charlesworth and Longley (Genetics 112:359):

$s \approx -\delta u = \left[\frac{\bar{n}(u-v)}{2H} + \frac{\bar{n}\pi}{2(1-2\pi)} \right]$ where δu = change in the rate of transposition, n = copy number, u = rate of transposition, v = rate of excision per element, H = harmonic mean of the rate of transposition, π = sterility or lethality caused by the transposition. The spliceosomes, telomerases, and the ability of immunoglobulin genes to transpose may have originated from transposons. The whole-genome sequencings revealed the existence of transposable elements that were not detectable by the methods of classical genetics. About 3% of the *Drosophila* genome is transposable. A survey of 13,799 human genes revealed that 533 (~4%) included some type of a transposable element (Nekrutenko A, Li W-H 2001 Trends Genet 17:619). A survey of 25,193 human proteins revealed that 4,653 human genes carry similarities to sequences in putative transposable elements. Since during evolution many rearrangements have taken place, the exact number of contribution of the transposable elements is not easy to ascertain (Britten R 2006 Proc Natl Acad Sci USA 103:1798). Transposable elements frequently generate chromosomal aberrations such as deletions, duplications, inversions, translocations, etc. *Doc1420* LINE element of *Drosophila* can generate an adaptive pesticide resistance through truncation of a gene (Aminetzach YT et al 2005 Science 309:764).

Transposable Elements Animal: ▶copia, ▶P element, ▶LINE, ▶SINE, ▶hybrid dysgenesis, ▶R2Bm, ▶immunoglobulins

Transposable Elements, Bacterial: Bacterial transposable elements may be classified according to the Gram-negative host (Tn3, Tn5, Tn7, Tn10) or gram-positive host (Tn554, Tn916, Tn1545, Tn551 and Tn917, Tn4556, Tn4001). The large transposon such as Tn916 and Tn1545 are capable of conjugative-like transfer to other cells. ▶insertion elements, ▶non-plasmid conjugation

Transposable Elements Fungal: ▶Ty, ▶transposable elements yeast

Transposable Elements, Plants: ▶Ac-Ds, ▶Spm (En), ▶Dt, ▶Mu, ▶Tam, ▶TAG, ▶controlling elements, ▶somaclonal variation, ▶retrotransposons, ▶retrotransposon, ▶transposons, ▶Helitron, ▶pack-MULEs; Wessler SR 2001 Plant Physiol 125:149; Jurka J, Kapitonov VV 2001 Proc Natl Acad Sci USA 98:12315; Feschotte C et al 2002 Nature Rev Genet 3:329.

Transposable Elements, Yeast: ▶Ty [including δ , ▶ σ , ▶ τ], ▶ Ω , ▶mating type determination, ▶*Schizosaccharomyces pombe*

Transposant: An individual/line generated with the aid of a gene trap vector. ▶gene trap vector

Transposase: An enzyme mediating the transfer of transposable genetic elements within the genome. The transposase function may be a part of the transposable element or it may be provided from trans position for elements that are defective in the enzyme. The transposase of phage MU first cuts away the transposons from the flanking DNA. Then it inserts the cleaved ends into the new DNA target site. The conserved DD35E motif is essential for both of these reactions and a single active site is responsible for the cleavage as well as for the transfer (D: aspartic acid, 35: amino acids, E: glutamic acid). Before transposition the multimeric transpososome is assembled, including the transposon ends and proteins (such as the tetrameric MuA protein of bacteriophage Mu). ▶transposon, ▶transposable element, ▶Tn10, ▶cut-and-paste; Goldhaber-Gordon I et al 2003 Proc Natl Acad Sci USA 100:7509.

Transposition: The transfer of a chromosomal segment to another position. The transposition may be *conservative* when the segment (transposon) is simply transferred to another location or it may be *replicative* when a newly synthesized copy is moved to another place while the original copy is still retained where it was (see Fig. T101).

Figure T101. A model of transposition by IS10 of transposable element Tn10. (Courtesy of Mizuuchi K. From Kennedy AK et al 2000 Cell 101:295)

Transposition usually requires that both terminal repeats of the transposon would be intact. *One-sided transposition*—when one terminal repeat is lost—may still be feasible by replicative transposition. In *Drosophila*, ~80% of the mutations were attributed to transpositions. *Non-linear transposition* takes place when the transposon ends are located in different molecules. The latter type of event may generate diverse chromosomal rearrangements. ▶insertion element, ▶transposons, ▶transposable elements, ▶cut-and-paste, ▶Tn, ▶hybrid dysgenesis, ▶immunoglobulins, ▶mating type determination in yeast, ▶*Schizosaccharomyces pombe*, ▶transposon—recombination

Transposition Immunity (target immunity): In target immunity, the transposable element does not move into a replicon, which already carries another transposon or the inverted terminal repeats of a transposon. Transposition immunity is overcome by high expression of the transposase or defects in the terminal repeats of the resident transposon. Transposition of Tn7 is inhibited by the presence of Tn7 sequences within the same replicon. ▶transposition, ▶transposable elements, ▶Tn3, ▶insertional mutation; Manna D, Higgins NP 1999 Mol Microbiol 32:595.

Transposition Induction: In transposition induction, the normal rate of transposition of the Ty1 yeast retrotransposon is about 10^{-5} – 10^{-7} per element per cell division, its rate can be substantially increased if in a multicopy plasmid pGTy1. The Ty element is under the control of an inducible *GAL1* promoter. Transposition of Ty is controlled also by *RAD25* and *RAD3*. ▶Ty, ▶galactose utilization, ▶RAD3, ▶RAD25, ▶transposase; Staleva L, Venkov P 2001 Mutation

Res 474:93; Eichenbaum Z, Livneh Z 1998 Genetics 149:1173.

Transposition Site: The target of insertion is generally not random. The bacterial Tn10 prefers 5'-NGCTNAGCN-3'. The mariner transposon selects CAYA-TA-TRTG environment. Tn5 prefers a palindrome-like sequence flanked by A and T: A-GNTY-WRANC-T. The insertion element IS231A likes a site within an S-shaped DNA. Retroviral elements show predilection for DNA around nucleosomes and cruciform DNA. Bacteriophage Mu is inserted nearly at random yet some preferences for a pentamer within a 23–24-bp tract and avoidance of the *lacZ* control region has been noted. ▶transposons, ▶cruciform DNA, ▶nucleosomes, ▶Mu bacteriophage; Haapa-Paananen S et al 2002 J Biol Chem 277:2843.

Transposome: A complex of a transposase, the transposon, and other proteins mediating the insertion of the transposon into a target DNA. ▶transposon, ▶transposase; Hoffman LM et al 2000 Genetica 108:19.

Transposon: ▶Tn, ▶transposable elements, ▶retroposon, ▶retrotransposon, ▶TRIPLES

Transposon, Conjugative: A diverse group of broad host-range transposons varying in size from 18 to over 150 kb double-stranded DNA. They occur in different *Bacteroides* species. After excision they form a circular intermediate molecule that can integrate into the DNA of another cell by a conjugation-like process. When a transposon excises it carries along a 6 bp adjacent sequence of the host. The excision may be followed by restitution—without duplication—at the original host site or it may leave a footprint at the original location. Transposons may trigger the movement of other transposable elements. ▶transposable elements, ▶plasmid, ▶conjugation; Hinerfeld D, Churchward G 2001 Mol Microbiol 41:1459.

Transposon Footprint: Short insertions left behind in the original target after the transposon exited from the sequences. These nucleotides may be the consequence of the genetic repair after excision, e.g., the sequence before the insertion CTGGTGGC after excision may become: CTGGTGGC-TGGTGGGC or CTGGTGGGcTGGTGGC. ▶transposable elements, ▶second cycle mutation; Plasterk RH 1991 EMBO J 10:1919; Hare RS et al 2001 J Bacteriol 183:1694.

Transposon Mutagenesis: As per transposon mutagenesis, transposable and insertion elements can move in the genome (mobile genetic elements) and may insert within the boundary of genes. Such an insertion, by virtue of interrupting the normal reading frame, may

eliminate, reduce, or alter the expression of the gene and the event is recognized as a mutation. Recently, it has been shown that many of the insertions do not lead to observable changes in the expression of the genes, or their effect is minimal and only sequencing of the target loci reveals their presence. Mutations so generated have great advantage for genetic analysis because the insertion serves as a tag on the gene permitting its isolation and molecular study. Many of the insertions are retrotransposons and in plants commonly located within introns. In animals the comparable elements are frequently within intergenic regions. In *Caenorhabditis*, transposons—but not retrotransposons—tend to be located within sequences of high recombination. In *Drosophila*, such differences were not confirmed. Coupling a site-specific DNA-binding domain (DBD) of a polydactyl zinc-finger protein E2C to the *Sleeping Beauty* transposase produced a transposable element specific to human chromosome 17 (Yant SR et al 2007 Nucleic Acids Res 35(7):e50). ▶[gene tagging](#), ▶[insertional mutation](#), ▶[scanning transposon mutagenesis](#), ▶[transformation](#), ▶[TraSH](#), ▶[labeling](#), ▶[gene isolation](#), ▶[plasmid rescue](#), ▶[suicide vector](#), ▶[retrotransposon](#), ▶[retroposon](#), ▶[sleeping beauty](#); Mills DA 2001 Curr Opin Biotechnol 12:503; Dupuy AJ et al 2001 Genesis 30:82.

Transposon—Recombination: In transposon recombination, transposons may induce various types of chromosomal rearrangements and deletions in both prokaryotes and eukaryotes. The bacterial transposons (Tn), the *Drosophila* P elements, the budding yeast Ty elements, and under some conditions (but not under others) the plant transposons too may enhance a somewhat or even dramatically homologous recombination at the sites of their insertion. The recombination in plants may precede meiosis. ▶[transposon](#), ▶[Tn](#), ▶[hybrid dysgenesis](#), ▶[Ty](#); Xiao Y-L et al 2000 Genetics 156:2007.

Transposon Tagging: Tagging a gene by the insertion of a transposon. The insertion disrupts the continuity of the gene, causing a mutation and thereby the success of the tagging is identified by the phenotype. Subsequently, using the labeled transposon as a probe can aid the isolation of the gene. ▶[transposon mutagenesis](#), ▶[probe](#), ▶[gene isolation](#); Long D, Coupland G 1998 Methods Mol Biol 82:325; Pereira A, Aarts MG 1998 Methods Mol Biol 82:329; Kumar A et al 2000 Methods Enzymol 328:550.

Transposon Vector: A transposon vector can be used for introducing genes into the somatic cells of animals by microinjection into embryos of vertebrates or into invertebrates. These vectors must include transposase function, selectable marker(s) and a chosen gene.

The *Drosophila* Mariner-like, Tc1-like or Sleeping Beauty vectors appeared more successful and safer than viral vectors. ▶[vectors](#), ▶[mariner](#), ▶[hybrid dysgenesis](#), ▶[piggyBAC](#), ▶[Sleeping Beauty](#), ▶[P-element vector](#); Izsvak Z et al 2000 J Mol Biol 302:93; Grossman GL et al 2000 Insect Biochem Mol Biol 30:909.

Transposon-based Sequencing: The transposon-based sequencing is used primarily for sequencing cDNA. Various transposons (Mu, Tn5) or repetitive DNAs are introduced at random into the cells and isolated on the basis of the selective markers (antibiotic resistance) within the transposon. Sequencing employs primers, which are specific for the ends of the transposon. ▶[EST](#), ▶[DNA sequencing](#); Yaron SN et al 2002 Nucleic Acids Res 30:2460; Shevchenko Y et al 2002 Nucleic Acids Res 30:2469.

Transposons, Animal: ▶[transposable elements animal](#)

Transposons, Bacterial: DNA segments which can insert into several sites of the genome and contain gene(s) besides those required for insertion; they are generally longer than 2 kilobases. It has been suggested that the introns of eukaryotic cells might have been introduced into the genes by broad host-range phages or transposons. ▶[Tn](#), ▶[insertion elements](#), ▶[accessory proteins](#)

Transposons, Fungal: ▶[Ty](#)

Transposons-Controlling Elements, Plant: The major transposable elements in maize are *Ac-Ds*, *Spm*, *Dt*, and *Mu*. Besides these, there are much less well defined controlling elements: *Bg* (*Bergamo*), *Fcu* (*Factor Cuna*), *Mr* (*Mutator of R*), *Mrh* (*Mutator of a1-m-rh*), *Mst* (*Modifier of allele R-st*), *Mut* (controlling element of *bz1-m-rh*), *Cy* (regulatory element of *bz1-rcy*). ▶[controlling elements](#), ▶[Ac-Ds](#), ▶[Spm](#), ▶[Dt](#), ▶[Mu](#), ▶[Tam](#), ▶[Ta](#)

Transresponder: The ABL oncogene is activated (transresponds) by translocation to BCR in the Philadelphia chromosome and causes chronic myelogenous leukemia in more than 90% of the cases. ▶[BCR](#), ▶[ABL](#), ▶[Philadelphia chromosome](#), ▶[leukemia](#); Gardner DP et al 1996 Transgenic Res 5:37.

Trans-Sensing: Trans-sensing is an interaction between somatically “paired” homologous chromosomes affecting gene expression in diploids. ▶[transvection](#); Tartof KD, Henikoff S 1991 Cell 65:201.

Transsexual: A transsexual has an innate desire to change her/his anatomical sex to the other form. The volume of the central subdivision of the bed nucleus of the strial terminals of the brain is larger in males than in females. In male-to-female transsexuals, this particular area of the brain is female sized. Thus this

anatomical condition may be a determining factor for transsexualism and sex hormone production. Estrogen family drug treatment may cosmetically help to improve the size of the breast. ►[sex determination](#)

Transsomic Line: The transsomic line carries micro-injected chromosomal fragments in the cell nucleus.

Trans-Splicing: Trans-splicing is the splicing together of exons that are not adjacent within the boundary of the gene but are remotely positioned and may be even in different chromosomes. ►[introns](#), ►[regulation of gene activity](#), ►[tau](#), ►[SL1](#), ►[SL2](#); Vandenberghe AE et al 2001 *Genes Dev* 15:294; Denker JA et al 2002 *Nature [Lond]* 417:667.

Transthyretin: A homotetrameric 55 kDa protein in the brain facilitating thyroxine transport and mediating association of retinol to retinol-binding protein. It also binds the β fragment of amyloid proteins and is instrumental in Alzheimer disease and other amyloid diseases. Genistein is an inhibitor of the dissociation of the transthyretin tetramers and also inhibits amyloidogenesis (Green NS et al 2005 *Proc Natl Acad Sci USA* 102:14545). Thus consumption of soybean products may be preventive or therapeutic. ►[goiter](#), ►[retinol](#), ►[Alzheimer disease](#), ►[prion](#), ►[amyloidosis](#); Li MD et al 2000 *J Neurosci* 20:1318.

Trans-Translation: Trans-translation may occur if the stop codon and the preceding end of the mRNA are lost and using another template RNA completes the translation. ►[recoding](#), ►[tmRNA](#); Lee S et al 2001 *RNA* 7:999; Bessho Y et al 2007 *Proc Natl Acad Sci USA* 104:8293.

Trans-Vection: ►[cis-vection](#), ►[transacting element](#), ►[cis-trans effect](#)

Transvection: A synopsis-dependent modification of activity in “pseudoalleles.” In paired chromosomes genes in trans position may affect the expression of an allele. It has also been called trans-sensing. It has been interpreted as the result of interaction between DNA binding proteins attached to the two synapsed promoters. ►[co-suppression](#), ►[RIP](#), ►[trans-sensing](#), ►[pseudoalleles](#); Lewis EB 1951 *Cold Spring Harbor Symp Quant Biol* 16:159; Matzke M et al 2001 *Genetics* 158:451; Duncan IW 2002 *Annu Rev Genet* 36:521.

Transversion Mismatch: A mispairing involving either two purines or two pyrimidines. ►[mismatch](#), ►[transition mismatch](#)

Transversion Mutation: The substitution of a purine for a pyrimidine, or a pyrimidine for a purine in the genetic material. ►[base substitutions](#), ►[base substitution mutations](#); Freese E 1959 *Brookhaven Symp Biol* 12:63.

Trap: The same as CD40 ligand.

TRAP (testis-specific cytoplasmic poly[A] polymerase): TRAP controls germ cell morphogenesis. ►[poly-adenylation signal](#); Kashiwabara S-I et al 2002 *Science* 298:1999.

TRAP (tryptophan RNA-binding attenuation protein): In *Bacillus subtilis* when activated by L-tryptophan, this protein binds to the mRNA leader causing a termination of transcription. This is in contrast to the situation in *E. coli* where the attenuation is brought about by an altered secondary structure of the nascent RNA transcript. Some sort of attenuation takes place also in eukaryotes but the mechanism of that is not entirely clear yet.

The *mtrB* gene in *B. subtilis* encodes the TRAP protein containing 11 identical subunits and it binds single-stranded RNA. The β -sheet subunits form a wheel-like structure with a hole in the center and tryptophan is attached to the clefts between the β -sheets resulting in circularization of the RNA target in which eleven U/GAG repeats are bound to the surface of this ondecamer (11 subunit) protein modified by tryptophan. TRAP may regulate both transcription and translation. Similar mechanisms occur also in some other bacterial species. ►[tryptophan operon](#), ►[attenuator region](#); structure in: Antson AA et al 1999 *Nature (Lond)* 401:235; Yakhnin AV, Babinzke P 2002 *Proc Nat Acad Sci USA* 99:11067; Chen G, Yanofsky C 2003 *Science* 301:211; Gollnick P et al 2005 *Annu Rev Genet* 39:47.

TRAP/DRIP/ARC: A part of a multiprotein complex of transcriptional regulators. (See Crawford SE et al 2002 *J Biol Chem* 277:3585).

Trapoxin: An inhibitor of histone deacetylase. ►[histone deacetylase](#)

TRAPP: A Golgi-associated protein for docking vesicles. ►[Golgi](#), ►[vesicles](#)

Trapping Poly-A Tails: In the process of trapping poly-A tails, the UPAS Trap suppresses nonsense-mediated RNA surveillance and permits targeting transcriptionally silent genes in embryonic stem cells. ►[nonsense-mediated RNA surveillance](#), ►[stem cells](#); Shigeoka T et al 2005 *Nucleic Acids Res* 33(2):e20.

Trapping Promoters: When a promoterless structural gene is inserted into a host genome with the assistance of a transformation vector, the inserted sequences may become “in-frame” located within the host chromosome and a host promoter may drive the transcription of the foreign gene that in the vector had no promoter. Since the promoter and upstream regulatory elements control the transcription, directly

or in association with transcription factors, the expression pattern (timing, tissue site) may be altered and the intensity of expression may be increased or decreased according to the nature of the promoter (see Fig. T102). ▶gene fusion, ▶transcriptional gene fusion vectors, ▶translational gene fusion vectors, ▶read-through proteins, ▶gene trapping, ▶expression trapping, ▶targeted trapping, see photo; Medico E et al 2001 *Nature Biotechnol* 19:579; mouse gene trap consortium (IGTC): www.genetrap.org; splinkerette; mouse embryonic stem cell trap library: <http://baygenomics.ucsf.edu>.

Figure T102. Transgenic tobacco seedlings segregate for kanamycin-sensitivity and resistance. A promoterless vector introduced the aminoglycoside gene into the cells. The structural gene was expressed only when it trapped a tobacco promoter. The strength of the promoters varied and consequently the degree of resistance too. Each Petri plate was divided into two sections and in one section all the small, bleached, sensitive seedlings died. (From Yao Y, Rédei GP, unpublished)

TraSH (transposons site hybridization): Genes are disrupted by transposons and changes in functions are compared—by microarray hybridization—to that in the wild type genome. ▶transposons mutagenesis, ▶microarray hybridization

Trastuzumab/Herceptin: is a monoclonal antibody used for specific cancer therapy. A new generation of HER2 breast cancer drug is Lapatinib. ▶biomarker, ▶Herceptin

Traveler's Diarrhea: is caused generally by bacterial (*E. coli*, *Salmonella*) infection.

TRCF (transcription repair coupling factor): A eukaryotic repair helicase corresponding to *UvrA* in *E. coli*;

it is encoded by yeast gene *MFD* (mutation frequency decline, Li BH et al 1999 *J Mol Biol* 294:35).

TRD (transmission ratio distortion): ▶meiotic drive, ▶segregation distorter

TRE: Thyroid hormone responsive element in the rat growth hormone gene with a consensus of AGGTCA...TGACCT. ▶ERBA, ▶hormone response elements, ▶regulation of gene activity; Oofusa K et al 2001 *Mol Cell Endocrinol* 181:97.

Treacher Collins Syndrome (TCOF1): A dominant (human chromosome 5q32-q33) complex defect of the face with an incidence of $\sim 2 \times 10^{-5}$. Mutation in the treacle, a 26-exon phosphoprotein is involved in neural crest cell formation. Treacle affects mammalian ribosomal DNA transcription by interaction with an upstream binding factor, which controls RNA polymerase I (Valdez BC et al 2004 *Proc Natl Acad Sci USA* 101:10709; Dixon J et al 2006 *Proc Natl Acad Sci USA* 103:13403).

Treadmill Evolution: ▶Red Queen hypothesis

Treadmilling: Is the addition of microtubule subunits to the growing plus end and loss of subunits at the minus end. ▶microtubules, ▶dynamic instability; Shaw SL et al 2003 *Science* 300:1715.

TREC (TCR excision unit including the recombination signals): ▶TCR genes

Tree of Life: ▶evolutionary tree

Trees: ▶forest trees

Tree Edit Distance: The minimal weighted number of changes required to change one tree of descent into another. ▶string edit distance, ▶evolutionary tree

Trehalose (α -D-glucopyranosyl- α -D-glucopyranoside): A non-reducing disaccharide, which accumulates in the yeast cell wall under conditions of stress. The use of trehalose for platelet and other cell preservation by freeze-drying has applied significance. Trehalose 6-phosphate regulates starch synthesis in plants by post-translationally activating ADP-glucose phosphorylase (see Fig. T103) (Kolbe A et al 2005 *Proc Natl Acad Sci USA* 102:11118). ▶inflorescence; Darg AK et al 2002 *Proc Natl Acad Sci USA* 99:15898.

Figure T103. Trehalose

TREMBL: A computer annotated protein sequence extension of the SWISS-PROT. ▶[SWISS-PROT in databases](#)

***Treponema pallidum*:** Spirochete bacterium with completely sequenced (1998) genome of 1,138,006 bp including 1041 open reading frames. It is responsible for the potentially deadly disease of syphilis. Due to protective immunity, waves of infections occur with 8–11 year periods in the populations (see Fig. [T104](#)) (Grassly NC et al 2005 Nature [Lond] 43 3:417).

Figure T104. *Treponema*

Many of the nineteenth to twentieth century artists (Maupassant, Daudet), the famous philosopher Friedrich Nietzsche suffered from mental illness caused by the infection. *Treponema denticola* causes periodontal (bleeding gum) disease. ▶[leptospirosis](#), ▶[spirochetes](#); Fraser CM et al 1998 Science 281:375.

Trexon (transposed exon): Short duplicated modular units in the DNA with inverted terminal repeats. ▶[transposon](#), ▶[exon](#)

TRF: ▶[T cell replacing factor](#), ▶[a lymphokine](#)

TRF (thyrotropic release factor): ▶[corticotropin](#)

TRF1 (TATA-box-binding protein related factor): is a tissue- and gene-specific binding protein with preference for one of the two *Tudor* locus (2-[97]) promoters of *Drosophila*. The protein product of *tud*

has maternal effect and it is expressed mainly in the embryos and pupae. (See Takada S et al 2000 Cell 101:459; ▶[histones](#)).

TRF1: 60 kDa telomeric TTAGGG repeat binding protein negatively regulates telomere extension and facilitates its interaction with the telomerase enzyme. ▶[telomeres](#), ▶[telomerase](#), ▶[RAP](#), ▶[tankyrase](#); Nakamura M et al 2001 Curr Biol 11:1512.

TRF2: (telomeric repeat-binding factor-2): One of the proteins, which protect telomeric ends of the chromosomes. TRF2 inhibition may lead to apoptosis, mediated by p53 and mutated ataxia telangiectasia genes. TRF2 is associated with RAD50, MRE11 and BS1 proteins. Oxidative damage (e.g., 8-oxoguanamine lesion) greatly reduces the affinity of both TRF1 and TRF2 (Opresko PL et al 2005 Nucleic Acids Res 33:1230). TRF2 mutations predispose to premature aging, cancer and ultraviolet sensitivity (Muñoz P et al 2005 Nature Genet 37:1063). ▶[TRF1](#), ▶[telomeres](#), ▶[apoptosis](#), ▶[ataxia telangiectasia](#), ▶[p53](#), ▶[RAD50](#), ▶[Mre](#), ▶[oxidative DNA damages](#), ▶[Nijmegen breakage syndrome](#); Fairall L et al 2001 Mol Cell 8:351.

T-RFLP: The procedure has been successfully exploited for the estimation of genetic diversity within bacterial populations. It involves PCR amplification of a gene of interest (often 16S rRNA genes) with fluorescent dye-labeled primers, followed by multiple single restriction digests done in parallel. The resulting fragments are then separated by capillary electrophoresis with an internal size standard to determine the lengths of the terminal (fluorescently labeled) fragments. Each distinct terminal restriction fragment is considered an operational taxonomic unit (OTU), thus the choice of restriction enzymes can impact the number of OTUs observed in each sample and the calculation of diversity statistics (Collins RE, Rocap G 2007 Nucleic Acids Res 35:W58). ▶[RFLP](#); restriction enzyme choice: <http://rocaplab.ocean.washington.edu/tools/repk>.

Trg: Bacterial transducer protein with attraction to ribose and galactose. (See Beel BD, Hazelbauer GL 2001 Mol Microbiol 40:824).

Triabody: Trimeric antibody built of three single chain pairs of the variable heavy and light chain regions of antibody. ▶[antibody chimeric](#), ▶[diabody](#), ▶[recombinant antibody](#); Le Gall F et al 1999 FEBS Lett 453 (1–2):164.

Triacylglycerols (synonym triglycerides): are uncharged esters of glycerol and thus called also neutral fats. Triglycerides are energy storage compounds and contain four times as much energy in the human body than all the proteins combined. By lipase, they are

hydrolyzed into glycerol and fatty acids. Lipolysis is controlled by cAMP in the adipose (fat) cells. Insulin inhibits lipolysis. Impaired long-chain fatty acid oxidation, triglyceride breakdown defects, triglyceride transfer (MTP, 4q22-q24) in abetalipoproteinemia, hypertriglyceridemia (15q11.2-q13.1) a dominant hyperlipidemia and it is a risk for heart disease, etc. are diseases involved in triglyceride metabolism. ►epinephrine, ►norepinephrine, ►glucagon, ►adrenocorticotrophic hormone, ►fatty acids, ►triglycerol; Zimmermann R et al 2004 Science 306:1383.

Triad Test: is an association mapping procedure where the two parents and the proband are tested, and it may involve unrelated control(s). ►association mapping; Epstein MP et al 2005 Am J Hum Genet 76:592.

Triage: Assignment of priorities in medicine or in the regulation of cellular metabolism.

Triallelic Inheritance: The manifestation of the recessive disease e.g., the Bardet-Biedl syndrome may require the expression of three mutant alleles. ►digenic disease, ►Bardet-Biedl syndrome, ►epistasis; Katsanis N et al 2001 Science 293:2256.

Triangulation Number: Represents the number of protein subunits (facets) in an icosahedral viral capsid. ►icosahedral, ►capsid; Paredes AM et al 1993 Proc Natl Acad Sci USA 90:9095.

Tribe: Descendants of a female progenitor or a taxonomic group below a suborder or a group of primitive people with a common origin, culture and social system.

Tribolium castaneum (n = 10, 200 Mb): red flour beetle, object of cytological and population genetics studies. The body segmentation gene (*mlpt*) produces polycistronic mRNA (Savard J et al 2006 Cell 126:559). For a genetic map see Beeman RW, Brown SJ 1999 Genetics 153:333; Klingler M 2004 Current Biol 14:R639; <http://www.ksu.edu/tribolium/>; <ftp://ftp.ncbi.nlm.nih.gov/genomes/>; <http://www.bioinformatics.ksu.edu/BeetleBase/>; <http://www.intlgenome.org/viewOrganisms.cfm?organismID=1000185>.

TriC: is a ring complex of eukaryotic chaperonin. TriC-P5 is synonymous with CCT γ , Bin2p, Cct3p. ►chaperonins; Dunn AY et al 2001 J Struct Biol 135:176.

Tricarboxylic Acid Cycle: ►Krebs-Szentgyörgyi cycle

Trichocyst: An organ of protozoa that may extrude fibrous shafts and may serve as an anchor or defensive or offensive tool.

Trichogen Cell: ►tormogen

Trichogyne: Hypha emanating from the protoperithecium, to what the conidia are attached prior to fertilization in some ascomycetes. ►hypha, ►conidia

Trichome: Hair or filament in plants, algae and animals; some plant hairs may be single filaments or they may have tripartite termini (see Fig. T105). (See Szymanski DB et al 2000 Trends Plant Sci 5:214, photo above).

Figure T105. Trichome

***Trichomonas vaginalis*:** Is an infectious, non-mitochondrial protozoan parasite of the human female and male sexual organs and urinary tract and it is transmitted by sexual intercourse (see Fig. T106). It may cause severe discomfort. Other species may infect domestic animals and also birds and invertebrates. *Trichomonas* and other protists do not have the regular type mitochondria but only mitosomes. The sequenced genome of *T. vaginalis* is about 176 megabase with a predicted protein-coding gene number of 59,681, 479 tRNA and about 250 rRNA genes (Carlton JM et al 2007 Science 315:207). ►mitosome, ►Entamoeba, ►Giardia, ►Protozoa

Figure T106. Trichomonas

Trichorhinophalangeal Syndrome (TRPS1): Dominant or recessive human chromosome 8q24 defect involving multiple exostoses (bone projections), mental retardation, protruding ears, sparse hair on the scalp, bulbous nose and short stature. Mutation in a zinc-finger protein gene is responsible for TRPS1. TRPSIII is most severe ►Langer-Giedion syndrome

Trichostatin A: An antifungal antibiotic, an inhibitor of histone deacetylase of yeast. Trichostatin may reverse the effect of methylation and activate methylated genes. In some instances low doses of

5-aza-2'-deoxycytidine along with trichostatin are required for substantial expression of originally methylated and silent cancer genes. Trichostatin increases the number of root hairs and their pattern of *Arabidopsis* (Xu C-R et al 2005 Proc Natl Acad Sci USA 102:14469). ▶[histone deacetylase](#), ▶[fragile X](#), ▶[root](#); Marks PA et al 2001 Curr Opin Oncol 13:477.

Trichothiodystrophy (TTD, 19q13.2-q13.3): is a collective name for autosomal recessive human diseases involving low-sulfur abnormalities of the hair. The *Tay syndrome* involves also ichthyosiform erythroderma (scaly red skin), mental and growth retardation, etc. The *Pollitt syndrome* (trichorrhhexis nodosa or trichothiodystrophy neurocutaneus) displays low cystin content of the hair, and the nails, and the head and the nervous system are also defective. Xeroderma pigmentosum IV includes trichothiodystrophy and sun- and UV-sensitivity. Also called PIBIDS. This type of mutation lacks helicase and excision repair activity because of the defect in the interaction between one of the xeroderma pigmentosum and the p44 protein subunit of the transcription factor TFIIH. Some TDD mutations are temperature-sensitive. ▶[hair-brain syndrome](#), ▶[xeroderma pigmentosum](#), ▶[Cockayne syndrome](#), ▶[excision repair](#), ▶[transcription factors](#), ▶[temperature-sensitive mutation](#), ▶[ichthyosis](#); Vermeulen W et al 2001 Nature Genet 27:299; de Boer J et al 2002 Science 296:1276.

Triclosan (trichlorinated diphenyl ether): Antibacterial and antifungal agent (blocking lipid biosynthesis) used in antiseptics, soaps, and other cosmetics.

Tricotyledony: is a relatively rare and generally not inherited developmental anomaly in plants (see Fig. T107). In some families of plants there is a higher than average tendency for the condition.

Figure T107. Tricotyledonous *Arabidopsis* seedling

Tricyclo-DNA: Tricyclo-DNA and -RNA can be used in antisense technologies to block selectively the expression of genes (see Fig. T108). ▶[antisense technologies](#); Renneberg D et al 2002 Nucleic Acids Res 30:2751.

Figure T108. Tricyclo-DNA

TRID: is a TRAIL decoy receptor. ▶[TRAIL](#)

Tricuspid Atresia: is an agenesis of the tricuspid valve, which connects the right atrium to the right ventricle of the heart. Some other heart defects may be associated with it. The condition is generally sporadic but some cases are familial and involve defects of the Zfp2/Fog2 Zinc-finger protein.

Triethylene Melamine (TEM): Alkylating agent (see Fig. T109). ▶[TEM](#)

Figure T109. Triethylene melamine

Trigger Factor (TF, ~48 kDa): is a prolyl isomerase enzyme (PPI) associated with the 50S ribosome unit of bacteria or with the GroL chaperone. It may aid translocation of molecules through the cytoplasmic outer membrane. In bacteria TF and DnaK may cooperate in protein folding but they are not indispensable at intermediate temperatures. Cyclosporin or FK506 does not inhibit TF and it is only moderately related to cyclophilins of FKBP. ▶[PPI](#), ▶[GroL](#), ▶[cyclosporin](#), ▶[FK506](#), ▶[cyclophilins](#), ▶[chaperone](#), ▶[GroEL](#), ▶[DnaK](#), ▶[Clp](#), ▶[protein sorting](#); Liu Z et al 2001 FEBS Lett 506:108; Patzelt H et al 2001 Proc Natl Acad Sci USA 98:14244; Ferbitz L et al 2004 Nature [Lond] 431:590.

Trigger Loop: is a part of RNA polymerase II complex just beneath the A site of ribosome; it triggers the formation of a phosphodiester bond during transcription of RNA and assures fidelity (Wang D et al 2006 Cell 127:941).

Triglyceride: Same as triacylglycerol.

Triglyceridemia: ►familial hypertriglyceridemia

Trihybrid Cross: The parental forms are homozygous altogether for 3 allelic pairs at (unlinked) loci, e.g., AABbDd × aabbDD and therefore in the F₂ 8 phenotypic classes may be distinguished. ►gametic array, ►Mendelian segregation

Tri-isosomic: in wheat, 20''+ i'', 2n = 43, ['' = disomic, '' = trisomic, i = isosomic]

Trillium: Species have one of the largest normal chromosomes (2n = 10) in plants, about 50 times larger than *Arabidopsis*, a plant with one of the smallest chromosomes (2n = 10) (see Fig. T110).

Figure T110. *Trillium* is from Sparrow AH, Evans HJ 1961 Brookhaven Symp Biol 14:76; *Arabidopsis* karyotype is the courtesy of Lotti Sears

TRIM (tripartite interaction motif): Retrovirus/lentivirus can be restricted after entry into the cells by the TRIM5α protein variants (Sayah DM et al 2004 Nature [Lond] 430:569). The TRIM proteins form a family and different members may occur in different mammals. ►retrovirus restriction factors; Song B et al 2005 J Virol 79:6111.

Trimester: Period of three months; the human pregnancy of 9 months includes 3 trimesters.

Trimethoprim (3,4-diamino-5-[3,4,5-trimethoxybenzyl]pyrimidine): An antibiotic.

Trimethylaminuria (1q23-q25): Defect in flavin monooxygenase and failure of detoxification of drugs and endogenous amines. Afflicted persons exhale fish odors.

Trimming: The processing of the primary RNA transcripts to functional mRNA or ribosomal and tRNA. The cleavage of pre-rRNA transcripts by RNase III into 16S, 23S and 5S rRNA as well as into the tRNAs contained within the spacer sequences of

the co-transcripts. The cleavage takes place at the duplex sequences forming the stem of the rRNA loops. ►post-transcriptional processing, *rrn* genes for diagram, ►introns

Trinomial Distribution: $(1 + 2 + 1)^n$ can be expanded to predict the segregation of the genotypic classes (note that the quotients within parentheses must not be added!)

$$1(1 + 2)^n + \frac{n!}{1(n-1)!}(1 + 2)^{n-1} + \dots + \frac{n!}{(n-1)!1}(1 + 2)^{n-(n-1)} + 1(1 + 2)^{n-n}$$

An example for three pairs of alleles:

$$1(1 + 2)^3 + \dots + \frac{3!}{1(2)!}(1 + 2)^2 + 1$$

$$1 + (3 \times 2) + (3 \times 4) + 8 + 3 \times (1 + 2 + 2 + 4) + 3 \times (1 + 2) + 1$$

When rewritten in a symmetrical distribution: 1:2:1:2:4:2:1:2:1:2:4:2:4:8:4:2:4:2:1:2:1:2:4:2:1:2:1 the 27 terms indicate that triple heterozygotes are 8, double heterozygotes 4, and single heterozygotes are 2 in a distribution in compliance with Mendel's law.

►binomial, ►multinomials

Trinucleotide Repeats: are microsatellite sequences displaying some clustering in yeast and other genes. In more than ten human neurodegenerative diseases CAG (glutamine codons) are repeated many times. The resulting polyglutamine (polyQ) oligomers seem to be the cause of the diseases or the disease accumulates the polyglutamine tracts. Diminished folding capacity of proteins seems to be involved in the trinucleotide repeat diseases (Gidalevitz T et al 2006 Science 311:1471). Autophagy more readily eliminates the polyglutamine tracts from the cytoplasm than from the nucleus (Iwata A et al 2005 Proc Natl Acad Sci USA 102:13135). The long polyglutamine sequences (most frequently beyond 35–40) interfere with CREB-dependent transcription by interacting with transcription factor TAF_{II}130. The polyglutamine proteins are more resistant to decay. Transglutaminase inhibitors (cystamine [←decarboxylated cysteine], monodansyl cadaverin [←decarboxylated lysine]) may alleviate apoptosis of the cells. RNAi may alleviate the problems normally associated with polyglutamine tracts (Caplen NJ et al 2002 Hum Mol Genet 11:175). Several small molecules are potent inhibitors of polyglutamine aggregation and suppress neurodegeneration in vivo (Zhang X et al 2005 Proc Natl Acad Sci USA 102:892). Unusual, common feature of these diseases that in successive generations the symptoms

appear earlier and with greater severity (anticipation) as gain-of-function mutations. The repeats form a hairpin structure and interfere with DNA replication. Also, the CpG sequences are likely to be methylated. Cis elements may contribute to instability (Cleary JD, Pearson CE 2003 Cytogenet Genome Res 100:25). The nature of the repeats may vary and may involve CGG, GCC, CAG, CTG sequences in different autosomes and the X chromosome, respectively. These repeats may expand (from a few [5–50] in the normal to hundreds of copies) in an unstable manner in the 5'-untranslated region of the FMR1 gene and cause translational suppression by stalling on the 40S ribosomal RNA. Defects in DNA repair may contribute to instability. Flanking sequences of the polyglutamine tracts affect the degree of misfolding and toxicity (Duennwald ML et al 2006 Proc Natl Acad Sci USA 103:11045). More than 40 human anomalies are attributed to changes in the repeats.

In *E. coli*, the larger expansions occur predominantly when the CTG trinucleotides are in the leading strands and deletions are mainly on the opposite lagging strands. The toxic effect of polyglutamine tracts can be genetically suppressed in *Drosophila* by proteins homologous to heat shock protein 40 and a tetratricopeptide, both containing chaperone-like a domain. The instability caused by the repeats is more common in meiosis than in mitosis. In yeast the CAG/CTG repeat meiotic instability is based on double-strand DNA break repair (see Fig. T111).

It has been suggested that the DNA polymerase stalls within the CTG-CAG repeat sequences and cause nicks and double-strand breaks that promote homologous recombination in lower and higher eukaryotes at 10% or higher frequency. Polyglutamine expansions can affect transcription and can be one of the causes of the disease (Helmlinger D et al 2006

TRIO (in human genetics): mother + father + child are available for study.

Trioma: ▶heterohybridoma

Triose: is a sugar with 3 carbon backbone.

Triosephosphate Isomerase Deficiency (TPI1): is encoded in human chromosome 12p13 but pseudogenes seem to be present at other locations. The level of activity of the enzyme varies. Null mutations are not expected to be viable since this is a key enzyme in the glycolytic pathway. The symptoms may be quite general weakness, neurological impairment, anemia, recurrent infections, etc. ▶glycolysis

Trip1 (thyroid hormone receptor): ▶Sug1

Triparental Human Embryo: Can be produced if a fertilized human egg nucleus is transferred into the egg of another female and implanted into a foster mother. The purpose of such an experiment would be to get rid of defective mitochondria of the first female and secure a healthy offspring. Such a procedure is not allowed in the USA but it has been approved in the United Kingdom in 2005. ▶multiparental offspring, ▶ART, ▶mitochondrial diseases in humans; Check E 2005 Nature [Lond] 437:305.

Tripeptide Discriminator (tripeptide anticodon): is part of the prokaryotic and eukaryotic translational release factors that recognize nonsense codons in mRNA and terminate protein synthesis. ▶release factor; Nakajamura Y, Ito K 2002 FEBS Lett 514:30.

Tripeptidyl Peptidase (TPPII): is a large protein complex outside the lysosomes with activity resembling the proteasome. ▶proteasomes

Triplasmy: is heteroplasmy for three different types of mtDNA. ▶heteroplasmy, ▶mtDNA

Triple A Syndrome: ▶achalasia-addisonianism-alacrima

Triple Helix Forming Oligonucleotides (TFO): May bind to polypurine-polypyrimidine tracts in the major groove of the DNA helix by Hoogsteen or reverse Hoogsteen bonding and prevent the access of transcription factors. This may block transcription and cleave the DNA but may enhance repair DNA synthesis. In the triplex sequences, mutation rate in SV40 increased more than an order of magnitude in the suppressor gene, supFG1, employed as reporter, with 30 nucleotide long AG sequences (AG30). Shorter sequences or oligonucleotides of all four bases were either not or were much less effective. The triplex structure in xeroderma pigmentosum or in the Cockayne syndrome cells was not effective for mutation enhancement, indicating the requirement of excision repair for the events. TFOs may be used for targeting specific genes and prevent their

transcription or to induce mutation. ▶TPO, ▶LNO, ▶DNA kinking, ▶triplex, ▶DNA repair, ▶SV40, ▶supF, ▶xeroderma pigmentosum, ▶Cockayne syndrome, ▶Hoogsteen pairing, ▶antisense technologies, ▶psoralen dyes, ▶locked nucleic acids, ▶pseudoknot, ▶targeting genes, ▶inhibition of transcription, ▶helix; Grimm GN et al 2001 Nucleosides Nucleotides Nucleic Acids 20:909.

TRIPLES (transposon-insertion phenotypes): is a database with information on phenotype, protein localization and expression on the results of transposon mutagenesis in yeast. ▶insertional mutation, ▶transposon; <http://ygac.med.yale.edu>.

Triplet Binding Assay: A historically important method to determine the meaning of genetic triplet codons. A single type of radioactively labeled amino acid, charged to the cognate tRNA was allowed to recognize and bind to ribosomes with mRNA attached. Each type of charged tRNA then recognized only the corresponding code and the ribosomes were then trapped on the surface of a filter. Synthetic polynucleotides (mRNA) of known base composition retained only the cognate aminoacylated tRNA and thus provided the base composition and sequence of the true coding triplets. (See Fig. T112, ▶genetic code; Nirenberg MW, Leder P 1964 Science 145:1399).

Triplet Code: ▶genetic code

Triplet Expansion: ▶trinucleotide repeats

Triplex: Three-stranded nucleic acid structure, e.g., an RNA oligo-nucleotide may bind within the strand or to double-stranded DNA and result in antisense effects. Triplex strands occur transiently in genetic recombination. Triplex forming oligonucleotides may increase somatic mutation and recombination by the mechanism of nucleotide exchange repair (see Fig. T113). Some DNA polymerases (T7, Klenow fragment) can elongate a DNA strand from primers forming triple helices of 9–14 deoxyguanosine-rich residues. Triplex-forming oligonucleotides (TFO) may be used for sequence-specific control of gene expression. ▶antisense RNA, ▶Hoogsteen pairing, ▶helix, ▶peptide nucleic acid, ▶TFO, ▶H-DNA,

Triplex: A polyploid with three dominant alleles at a gene locus. ►autopolyploid, ►trisomy

Triplicate Genes: Triplicate genes convey identical or very similar phenotype and in a diploid, when segregate independently, display an F₂ phenotypic ratio of 63 dominant and 1 recessive.

Triploblasts: Animals with ecto-, meso- and endodermal germ layers. ►diploblasts

Triploid: A cell or organism with three identical genomes. Triploids ($3x$) are obtained when a ($4x$) is crossed with a diploid ($2x$). The majority of edible bananas, several cherry and apple varieties, and many sterile ornamentals (chrysanthemums, hyacinths) are triploid. The seedless watermelons, produced by crossing tetraploids with diploids are triploids and have commercial value. Triploid sugar beets are produced in a large-scale agriculturally because they offer of $\approx 10\%$ or higher sugar yield per acre than the parental diploid varieties. Triploidy in humans may occur by fertilizing a diploid egg (digyny) by a monosomic (normal) sperm or by the union of a normal haploid egg and two spermatozoa (diandry). The green toad (*Bufo viridis*) is triploid but surprisingly reproduces bisexually. ▶ [trisomic](#); Zaragoza MV et al 2000 Am J Hum Genet 66:1807; Stöck M et al 2002 Nature Genet 30:325.

Triplo-X: Triplo-X females (XXX) occur in about 0.0008 of human births. Their phenotype is close to normal and they can conceive. Yet they are somewhat below average in physical and mental abilities although they tend to be somewhat tall. With an increasing number of X-chromosomes beyond 3, the adverse effects are further aggravated. ▶ [sex determination](#), ▶ [sex chromosomal anomalies in humans](#), ▶ [trisomy](#), ▶ [Turner syndrome](#); Barr ML et al 1969 Can Med Assoc J 101:247.

Trismus-Pseudocamptodactyly Syndrome (17p13.1): Camptodactyly, arthrogryposis, foot deformity, and failure to open the mouse completely due to defect in the myosin heavy chain gene (MYH8). ▶ [camptodactyly](#), ▶ [arthrogryposis](#), ▶ [myosin](#); Veugelers M et al 2004 New England J Med 351:460.

Trisomic: A cell or organism with one or more chromosomes (but not all) represented three times. ▶ [trisomy](#), ▶ [trisomic analysis](#), ▶ [triploid](#)

Trisomic Analysis: Trisomics have one or more chromosomes in triplicate (AAA) and thus produce both disomic (AA) and monosomic (A) gametes for gene loci in those chromosomes (see Table T2).

Male transmission of the disomic gametes is usually poor, it rarely exceeds 1%.

The transmission of disomic gametes through females varies according to the chromosome (genes) involved and depends also upon environmental conditions; most commonly this transmission is $1/4$ or $1/3$ of the normal (monosomic) gametes. The few viable human sex-chromosome trisomics (XXX, XXY, XYY) are either sterile or have very poor fertility because of the failure of normal development of the ovaries and testes (gonadal dysgenesis). From a single alternative allelic pair (A/a), disomics produce either A or a gametes. In contrast, trisomics potentially produce a maximum of five kinds of gametes, three disomic and two monosomic. The frequency of these five types of gametes depends also on the distance of the gene from the centromere, i.e., whether *chromosome segregation* (no crossing over between gene and centromere) or *maximal* (see Table T3).

Table T2. Gametic output of trisomics

| Genotype ↓ | Chromosome segregation | | | | | Maximal equational segregation | | | | |
|---------------|------------------------|----|----|---|---|--------------------------------|----|----|---|---|
| | AA | Aa | aa | A | a | AA | Aa | aa | A | a |
| AAa (duplex) | 1 | 2 | 0 | 2 | 1 | 5 | 6 | 1 | 8 | 4 |
| Aaa (simplex) | 0 | 2 | 1 | 1 | 2 | 1 | 6 | 5 | 4 | 8 |

Table T3. Phenotypic proportions in the F₂ of trisomics (disomic and trisomic pooled)

| Transmission [‡] & genotype ↓ | Chromosome segregation | | | Maximal equational segregation | | |
|---|------------------------|------|-----------------|--------------------------------|------|---------|
| | Dom. | Rec. | aaa (%) | Dom. | Rec. | aaa (%) |
| DUPLEX (AAa) | | | | | | |
| Male and female | 35 | 1 | 0 | 22.04 | 1 | 1.39* |
| Female only | 17 | 1 | 0 | 13.40 | 1 | 1.39 |
| None | 8 | 1 | 0 | 8 | 1 | 0.00 |
| Simplex (Aaa) | | | | | | |
| Male and female | 3 | 1 | 11 [§] | 2.41 | 1 | 13.9* |
| Female only | 2 | 1 | 11 | 1.77 | 1 | 13.9 |
| None | 5 | 4 | 0 | 1.25 | 1 | 0. |

[‡]refers to transmission of the disomic gametes
^{*}1/576 tetrasomics (aaaa) are not included
[§]1/36 tetrasomic (aaaa) is not included
^{*}25/576 tetrasomics (aaaa) are not included

In order to obtain two identical recessive alleles from a duplex, the chromosomes must form trivalents and recombination must take place between the gene and the centromere, following which the anaphase I distribution must move the two exchanged chromosomes toward the functional megaspore (equivalent to secondary oocyte in animals). At the most favorable coincidence of these events, in only half of the cases can we expect the two identical alleles to move into the same megaspore (equivalent to egg in animals).

Thus, the maximal chance of having a tetrad with a double recessive gamete (*aa*) will be $1/3 \times 1/2 = 1/6$. These fractions are based on one reductional and two equational disjunctions at meiosis I ($1/3$), while two alternative disjunctions at anaphase II ($1/2$) are the determining factors of the outcome.

The phenotypic segregation can be derived from the gametic output by random combinations. One factor, the transmission difference between the female and male gametes, seriously alters the theoretically expected proportions (see Table. T4).

Table T4. Phenotypic ratios in test-cross progenies (trisomics + disomics)

| Genotypes of cross ↓ | Only female transmission of disomic gametes | No transmission of disomic gametes |
|-------------------------|---|------------------------------------|
| | Dom.: Rec. | Dom.: Rec. |
| AAa x aa | 5:1 | 2:1 |
| Aaa x aa | 1:1 | 1:2 |

The genetic behavior of all chromosomes not present in triplicate in the trisomics is consistent with disomy. When the trisomic individuals are phenotypically distinguishable per se (do not require cytological identification of the chromosomal constitution), trisomy may be used very effectively to assign genes to chromosomes, irrespective of their linkage relationship. The segregation in a duplex will

not be 3:1 but it will vary (most commonly) between 17:1 to 8:1, as predicted by the table. In this case, the gene *a* is located in the chromosome that is triplicated. Genes in the disomic set of chromosomes are expected to display 3:1 segregation. In case telotrisomics are crossed with disomics ($\text{---} \text{---} \text{---} a \text{---}$, $\text{---} \text{---} a \text{---}$, $\text{---} \text{---} A \text{---}$ x normal disomic *a/a*), the dominant allele will be very rare among the diploid offspring but may be expressed in every individual of $2n + \text{telochromosome}$. Mapping can be done also by properly constructed isotrisomics, tertiary trisomics, and compensating trisomics. Genetic mapping with the aid of multipoint trisomic data is feasible also in humans (see Fig. T116). ▶disomic, ▶monosomic, ▶gonadal dysgenesis, ▶chromosome segregation, ▶maximal equational segregation, ▶mapping by dosage effect, ▶trisomy, ▶Down's syndrome, ▶Patau syndrome, ▶Edwards syndrome; Rédei GP 1982 Genetics. Macmillan, New York; Li J et al 2001 Am J Hum Genet 69:1255.

Figure T116. Left: The four primary trisomics (1–4) and a telotrisomic (5) of *Arabidopsis*. At the lower right corner is a normal disomic individual ($2n$). All are in columbia wild type background, grown under short daily light periods. At right: The chromosome complement of a primary trisomic. Note the trivalent association at the upper right area. (The photomicrograph is the courtesy of Dr. Lotti Steinitz-Sears)

Trisomic, Complementing: Trisomic complementing can be of three types; one is an apparent trisomic only because it involves a normal biarmed chromosome, while the two other chromosomes are actually telosomes, representing the left and right arms of the intact, normal chromosome. The second complementing type also involves one biarmed normal chromosome, but the two telosomes represent a pair of identical arms; thus, in essence this case is very similar to that of a secondary trisomic, having three identical arms and one single different arm. In the third type, in a normal biarmed chromosome, the second chromosome has an arm identical to the first but its second arm is a translocated segment from a non-homologous chromosome, and the third chromosome has a different translocated arm linked

to the centromere and to an arm of a normal chromosome. ▶trisomic analysis; scheme from GP Rédei's Lecture Notes 1980.

Trisomic, Primary: In a primary trisomic, the chromosome number is $2n + 1$, and the triplicate homologous chromosomes are structurally normal. ▶trisomic analysis

Trisomic, Secondary: In a secondary trisomic, the extra chromosome is an isochromosome, i.e., its two arms are identical; such a chromosome is an isochromosome. ▶trisomic analysis, ▶isochromosome

Trisomic, Tertiary: In a tertiary trisomic, the extra chromosome is involved in a reciprocal translocation and is partly homologous with two standard chromosomes. ▶trisomic analysis

Trisomy: Trisomy involves one or more but not all chromosomes of a genome in triplicate; trisomics are aneuploids. They may arise by selfing triploids when some of the extra chromosomes are lost. Nondisjunction during meiosis may also lead to trisomic progeny. Trisomy may exist in various forms. The phenotype of the trisomics varies, depending upon what genes are in the trisome. The phenotype may be very close, almost indistinguishable from that of normal disomics, and in other cases it may be lethal. Only a few of the autosomal human trisomies permit growth and development beyond infancy. Trisomy 9 allows near normal life expectancy although it also involves developmental and mental retardation. Individuals with trisomy 21 (Down's syndrome) also reach adulthood but remain mentally subnormal. Trisomy 22 may exist in mosaic form and the afflicted individuals are retarded in growth and mental abilities. About 3/4 of the trisomy 8 cases are mosaics, mentally retarded, and affected by head abnormalities to a variable degree, according to the extent of mosaicism. Trisomics for chromosome 11 have a variable extra long arm in chromosome 11 and accordingly exhibit brain and other internal organ damage of variable extent. Trisomics for the long arm of chromosome 3 have a very short life and variable abnormalities in internal organs and body development and severe mental retardation. Trisomy for the short arm of chromosome 4 is characterized by serious malformations of the brain, head, extremities, genitalia, and such individuals usually die early. About 1/3 of the abortuses, due to autosomal trisomy, involve chromosome 16; these are never carried to term. Trisomy 13 (Patau's syndrome) and trisomy 18 (Edwards syndrome) are live-born but die very early. Trisomy 16 is responsible for about 7.5% of all spontaneous abortions. XYY trisomies are apparently never found in spontaneously aborted or stillborn fetuses. All other autosomal human trisomies lead to

abortion at various stages after conception. Sex-chromosomal trisomy generally does not compromise viability of humans yet such individuals are usually sterile and display gonadal dysgenesis and a variety of physical and most commonly mental retardation as well. The vast majority of trisomics are the result of disomic female gametes. Paternal nondisjunction accounts for only a very small frequency of autosomal trisomy. However, 80% of 45 + X monosomies involve the loss of a paternal sex chromosome. Analytical procedures of about 65% efficiency exist for the detection of trisomy during the first trimester (Wapner R et al 2003 *New England J Med* 349:1405).

Trisomy is useful in plants for assigning genes to chromosomes. Microcell-mediated chromosome transfer permits the inclusion into mouse cell of only fragments of the third chromosome. The fragments are produced by chromosome breakage with the aid of ionizing radiation. The size and content of the fragments so generated is beyond precise experimental control; nevertheless, information can be obtained about the effects of segments smaller than an entire extra chromosome. Homologous recombination by gene targeting would appear to be a more desirable tool for generating segments of designed contents. Unfortunately, the frequency of this type of recombination is low. A chicken pre-B cell line (DT40) is known, however with 3–4 orders of magnitude higher homologous recombination. Technology is available for the transfer of human chromosomes to these chicken cell lines. The truncated human chromosomes from the chicken cell lines can then be reintroduced into human cells in culture. Another approach is the construction of human artificial chromosomes and minichromosomes (see Fig. T117).

The presence of an extra chromosome in yeast involves a number of phenotypes that are independent of the identity of the individual extra chromosome; all of these include defects in cell cycle progression, increased glucose uptake, and increased sensitivity to conditions interfering with protein synthesis and protein folding. These phenotypes reflect the consequences of additional protein production, imbalances in cellular protein composition and proliferative disadvantage (Chan LY et al 2007 *Science* 317:916). ▶trisomics, ▶trisomic analysis, ▶Down syndrome, ▶Edwards, ▶Patau's, ▶Klinefelter syndromes, ▶sex determination, ▶sex-chromosomal anomalies in humans, ▶cat-eye syndrome, ▶aneuploidy, ▶targeting genes, ▶chromosome uptake, ▶human artificial chromosome, ▶minichromosome, ▶microcell; Hassold TJ, Jacobs PA 1984 *Ann Rev Genet* 18:69; Robinson WP et al 2001 *Am J Hum. Genet* 69:1245.

Figure T117. In the complementing trisomics there is only one normal representative of a particular chromosome. For the homologous arms it may be compensated by translocations containing jointly the entire chromosome (1) or by two complementary isochromosomes (2). The complementing trisomics (2). The complementing trisomics can also be used to assign genes to chromosome arms. In case (1) the predominant fraction in the $2n$ progeny is expected to be recessive because only the non-translocation strand is transmitted by the monosomic gamete. The wild-type allele (G) can be transmitted only after recombination. In contrast, the $2n+1$ progeny should be almost all wild type (except when recombination occurs between gene and centromere). In selfing of genotype (2) the $2n$ and most of the $2n+1$ progeny are expected to be of dominant phenotype; however, when recombination occurs between (q) and centromere, the recessive allele is included in the normal chromosome. Such a setup as (2) can be exploited only if the two telochromosomes are not distributed together in the majority of anaphases I's of meiosis

Trisomy, Segmental: ▶segmental aneuploidy

Tristetraprolin (TTP): A zinc-finger protein, inhibitory to TNF- α by destabilizing its mRNA, although TNF and agents that stimulate TNF stimulate its production too. TTP binds to A-U-rich (AUR) 3' untranslated sequences and responds to cytokines and other regulatory molecules. The Dicer and Argonaute proteins of the RNAi and microRNA pathways are also required for the AUR decay (Jing Q et al 2005 *Cell* 120:623). TTP and several homologous proteins control also apoptosis. ▶TNF, ▶zinc fingers, ▶DNA-binding protein domain, ▶RNAi, ▶antiviral protein; Johnson BA, Blackwell TK2002 *Oncogene* 21:4237.

Tritanopia: ▶color blindness

Tritelosomic: Tritelosomic occurs in wheat, $20'' + t'''$, $2n = 43$, [$''$ = disomic, $'''$ = trisomic, t = telosomic].

Trithorax: *Drosophila* gene (3–54.2) regulating embryonic development (head, thorax, abdomen). Some of the alleles cause homeotic developments. The heterozygotes for the *trx^D* mutation display patchy variegation. ▶developmental-regulator effect variegation, ▶homeotic genes, ▶mll, ▶bithorax, ▶polycomb, ▶SET motif, ▶epigenesis, Petruk S et al 2001 Science 294:1331.

Triticale: A synthetic species produced by crossing wheat (*Triticum*) and rye (*Secale*) and doubling the chromosome number. The wheat parent may be tetraploid (2n = 28) or hexaploid (2n = 42) and the rye is generally diploid (2n = 14). Therefore, the amphidiploids may have the chromosome number of either 2n = 42 (hexaploid) or 2n = 56 (octaploid). As a crop variety, the former is used. On some soils suitable primarily for rye, the *Triticale* may provide grains with a milling quality approaching that of wheat. The new hybrids generally have shrunken kernels because some rye genes cause poor development of the endosperm. Breeding efforts have largely solved these problems and the commercial varieties have rather plump grains. ▶*Triticum*, ▶*Secale*, ▶amphidiploid, ▶chromosome doubling, ▶species synthetic; Gustafson JP 1987 Plant Breed Rev 5:41.

Triticalsecale: ▶*Triticale*

Triticum (common wheat and relatives): *Triticum* form a series of allopolyploids (see Table T5) (Huang S et al 2002 Proc Natl Acad Sci USA 99:8133). The common bread wheat, *T. aestivum* (both winter and spring forms), and the *T. durum* (*T. turgidum*) are used mainly for various pastas (macaroni, spaghetti, etc). The wheat kernel contains ca. 60–80% carbohydrates

(starch), 8–15% protein that is usually low in lysine, tryptophan, and methionine (see Fig. T118). Some wild relatives of the cultivated wheats produce kernels with higher amounts of protein than the commercial varieties, and chromosomal engineering can transfer these favorable traits. Wheats are the staple food for about 1/3 of the human population. ▶allopolyploids, ▶polyploidy, ▶monosomic analysis, ▶nullisomic, ▶glutenin, ▶celiac disease; Sears ER 1974 Handbook of Genetics. Figure T118. Wheat species: From right to left: *Triticum monococcum*, *T. turgidum* (*durum*), *T. timopheevi*, *T. aestivum* (Chinese Spring [most widely used for cytogenetic studies]), *T. compactum*, *T. spelta*. (Courtesy of Dr. Carlos Alonso-Arnedo)

Tritium (H^3): ► **isotopes**

Triton X-100: A non-ionic detergent (MW 537). It used for the extraction of proteins and the solubilization of biological materials. The reduced form is preferred when spectrophotometric measurement is required. Molar absorption is 1.46×10^3 at pH 8, 20°C in 1% sodium dodecylsulfate (SDS) at 275 nm. Ammonium cobalthiocyanate reacts with it as a blue precipitate.

Tritordeum: An allohexaploid hybrid of tetraploid wheat (A, B genomes) and barley (H) of allooctaploid (ABDH) constitution. ► *Triticum*, ► *Hordeum*, ► **allopolyloid**; Hernandez P et al 2002 Genome 45:198.

Tritryp: ► **trypanosomatids**

Trituration: The disintegration into cells or homogenization of tissues or mixing different components of various materials.

Trivalent: In a trisomic or polyploid individual, three chromosomes may associate during meiotic prophase (see Fig. T119). In the trivalent association at any particular place, only two homologous chromosomes can pair, however, at a specific time and site.

Figure T119. Trivalent

trk (TRK) Oncogene: The product of the TRK gene is a receptor in membranes (tyrosine kinase activity) for NGF (nerve growth factor). It is localized to human chromosome 1q23-q24. TRK affects axonal and dendritic growth, synapsis, cytoskeleton assembly, membrane traffic, signal transduction, etc. ► **nerve growth factor**, ► **ovary**; Nakagawara A 2001 Cancer Lett 169:107; Huang EJ, Reichardt LF 2003 Annu Rev Biochem 72:609.

T

tRNA (transfer RNA): The shortest RNA molecule in the cell (ca. 3.8S), consisting of about 76 to 86 nucleotides. tRNAs carry amino acids to the ribosomes during protein synthesis. The majority of cells have 40 to 60 types of tRNAs because most of the 61 sense codons have their own tRNA in the eukaryotic cytosol. The tRNAs, which accept the same amino acid are known as *isoaccepting tRNAs*. In the human mitochondria, there are only 22 different tRNAs and in plant chloroplasts, about 30. tRNA is frequently called an adaptor molecule because it adapts the genetic code for the formation of the primary structure of protein. Rarely (ca. 1/3000), a tRNA is charged with the wrong amino acid, and in

these cases the complex is usually disrupted and the tRNA, recycled. The tRNA genes may occur in between ribosomal RNA genes (promoter - 16S - - tRNA - 23S - 5S - tRNA - tRNA...) or they frequently form independent clusters of different tRNA genes (promoter - tRNA¹ - tRNA² - tRNA³ - •). The different cognate tRNA groups are generally identified by a superscript of the appropriate amino acid, e.g., tRNA_{Met}. Sometimes, individual tRNA genes may be present in multiple copies. The tRNA gene clusters are transcribed into large primary molecules that require successive cleavage and trimming to form the mature tRNA. The endonuclease, RNase P (a ribozyme) recognizes the primary transcript, whether it is a single tRNA sequence or a cluster of rRNA or tRNA genes, and cleaves at the 5' terminus where the tRNA begins. For the tRNA to become functional, RNase D cuts at the 3'-end, and stops at a CCA sequence if any, or the 3'-end receives through post-transcriptional synthesis (by tRNA nucleotidyl synthetase) one, two, or three bases; thus, tRNA always ends with a 3'-CCA_{OH} sequence. This 3'-OH end becomes the amino acid attachment site of the tRNA (► **transfer RNA**). During the process of maturation, through modification of the original bases, thiouridine (S4U), pseudouridine (ψ), ribothymidine, dihydrouridine (DHU), inosine (I), 1-methyl-guanine (m¹G), 1-dimethyl-guanine (m¹dG), and N⁶-isopentenyl adenosine (i⁶A) may be formed within the tRNA sequence. ► **transfer RNA**, ► **amino acylation**, ► **aminoacyl-tRNA synthetase**, ► **protein synthesis**, ► **trimming**, ► **ribozyme**, ► **intron**, ► **pseudouridine**, ► **ribothymidine**, ► **dihydrouridine**, ► **isopentenyladenosine**, ► **hypoxanthine [for inosine]**, ► **mitochondrial diseases in humans**, ► **tRNA nucleotidyl transferase**; Söll D, Rajbahandary UL (Eds.) 1994 tRNA, Structure, Biosynthesis and Function. AMS Press, Washington, DC; <http://medlib.med.utah.edu/RNAmods/>.

tRNA Cleavage: In tRNA cleavage, T even phages may cripple a bacterial host tRNA and the viral-coded isoaccepting tRNA is then substituted for that of the host. (See Amitur M et al 1987 EMBO J 6:2499; Kaufmann G 2000 Trends Biochem Sci 25(2):70; Meidler R et al 1999 J Mol Biol 287:499).

tRNA Deacylase: tRNA deacylase cuts off the tRNA D-amino acids from the polypeptide chain after the complex reaches the P site on the ribosome. ► **protein synthesis**, ► **aminoacyl-tRNA synthetase**; Ferri-Fioni ML et al 2001 J Biol Chem 276:47285.

tRNA Mimicry: In tRNA mimicry, certain set of translation factor proteins resemble tRNA in shape and may even mimic tRNA in deciphering

the genetic code. (See Nakamura Y 2001 J Mol Evol 53(4–5):282).

tRNA Nucleotidyl Transferase: Attaches after transcription CCA-3'-OH to the 3'-end of the amino acid accepting arm of tRNA without relying on a template. Before building this 3'-end of the tRNAs a nuclease must remove the tail of the primary transcript at a 'discriminator' position, which may be the 73th base. Some prokaryotic tRNA transcripts already contain CCA ends and thus the tRNA nucleotidyl transferase is not indispensable yet advantageous because it may repair the amino acid acceptor. The CCA transfer enzyme is not choosy; it recognizes all tRNAs irrespective their amino acid specificity. Most of the U2 snRNAs in humans also carries CCA ends. ▶tRNA, ▶transfer RNA; Vasil'eva IA et al 2000 Biochemistry [Moscow] 65:1157; Cho HD et al 2002 J Biol Chem 277:3447.

tRNA-SE: is a fast computer program capable of identifying 99–100% of tRNA genes in DNA sequences with extremely low false positives. It may be applied also to the detection of unusual tRNA homologs such as selenocysteine tRNA, tRNA pseudogenes, etc.

Trophectoderm: An extra-embryonic tissue at the blastocyst stage of mammalian development. It is also the founder cell population of the chorionic cells of the placenta. Its function is nutrient exchange and protection of the embryo against the maternal immune system. It also signals to gastrulation. ▶blastocyst, ▶chorion, ▶gastrula

Trophoblast: The surface cell layers of the blastocyst embryo connecting to the uterus.

Trophozoite: Growing and actively metabolizing cells of unicellular organisms vs. the cysts.

Trophophoresy: Propagating of species and disseminating them into new habitats by transferring them as food. ▶co-evolution

Tropic: Indicates after a word that something is aimed at it. e.g., T-tropic means that a virus targets T cells or directed at a site in some way.

Tropic Hormone: Stimulates the secretion of another hormone at another location.

Tropism: Growth of plants in the direction of some external factors.

Tropomodulin: Maintains actin filament growth by capping the pointed ends of the actin filaments. (See Littlefield R et al 2001 Nature Cell Biology 3:544).

Tropomyosin (TPM): is a skeletal muscle fiber protein with two chain α -helical coiled coil is essential for muscle filament stabilization and regulation of contraction. It bonds to actin. TPM3 is encoded at 1q22-q23. Endostatin binds tropomyosin. ▶troponin, ▶endostatin, ▶actin; MacDonald NJ et al 2001 J Biol Chem 276:25190; Brow JH et al 2005 Proc Natl Acad Sci USA 102:18878.

Troponin: Ca^{2+} -binding, regulatory polypeptides in the muscle tissue. Troponin C binds four molecules of calcium. Troponin I has an inhibitory effect on myosin and actin, and troponin I binds tropomyosin, an accessory protein. In the relaxed muscles, troponin I binds to actin and moves tropomyosin to the position where actin and myosin would interact at muscle contraction. When the level of Ca^{2+} is high enough troponin I action is blocked so myosin can bind actin again allowing the muscle to contract. Troponin C is related in function to calmodulin. In the *nemaline* (thread-like) *myopathy* at 19q13.4 the sarcomeric thin-filament protein (TNNT1) is truncated. This recessive/dominant, infant-lethal disease has an incidence of ~ 0.002 in the Amish populations. ▶calmodulin, ▶signal transduction, ▶myotonic dystrophy, ▶receptor tyrosine kinase, ▶myopathy, ▶arthrogryposis; Johnston JJ et al 2000 Am J Hum Genet 67:814; Hinkle A, Tobacman LS 2003 J Biol Chem 278:506, structure: Takeda S et al 2003 Nature [Lond] 424:35.

Trospa: ▶Lyme disease

TRP (transient receptor potential): plasma membrane ion channel components in control of active and passive Ca^{2+} stores and are activated by 1,4,5-trisphosphate receptors. ▶phosphoinositides, ▶SOC, ▶ion channels; Montell C et al 2002 Cell 108:595; Clapham DE 2003 Nature [Lond] 426:517; Vanketechalam K, Montell C 2007 Annu Rev Biochem 76:387.

Trp: ▶tryptophan operon, ▶tryptophan

TRPC (transient receptor potential channel): Protein sensors for temperature, osmolarity, mechanical stress, taste and axon guidance (Wang GX, Poo M-m 2005 Nature [Lond] 434:898).

TRRP (transactivation/transformation-domain associated protein): is a member of the ATM protein superfamily and it is a co-factor of cMYC-mediated transformation. The yeast homolog (Tra1) is a component of the histone acetyltransferase (HAT), SAGA, PCAF and NuA4. Trap is essential for normal development. (See terms mentioned; Herceg Z et al 2001 Nature Genet 29:206).

True Breeding: absence of segregation among the offspring.

Truncation: is a cut-off point; e.g., in artificial selection individuals before or beyond an arbitrarily determined point are discarded or maintained, respectively. Also a cloned eukaryotic-gene without a polyadenylation signal or an incomplete upstream control element may be called truncated. ▶selection; Crow JF, Kimura M 1979 Proc Natl Acad Sci USA 76:306.

Truncation Selection: Individuals with more mutations are more likely to be removed from the population and individuals with fewer mutations may survive and maintained.

Trypanosomatids: are three major species of protozoa, *Trypanosoma brucei* (~genes 9,068), *T. cruzi* (~12,000) and *Leishmania major* (8,311) protozoa spread by the tse-tse fly (*Glossina*) and other bug bites and cause sleeping sickness, Chagas disease and other serious diseases of animals and humans. As the Venn diagram below shows that about two third of their genes are very closely related (see Fig. T120) (El-Sayed NM et al 2005 Science 309:404). The three species (Trityp) have variable numbers of transposons; most of them are not intact, however. Various developmental stages are distinguished on the basis of the relative position of the flagella (basal flagella: trypomastigote, median: epimastigote, apical: promastigote, no flagella: amastigote). Flagellar motility of *Trypanosomes* in the blood stream is essential for survival and flagellar proteins may be targeted as a control measure of the parasites (see Fig. T121) (Broadhaed R et al 2006 Nature [Lond] 440:224). The *Trypanosomas* may reach a level of 10^9 – 10^{10} individuals per mL blood of mammals. The chromosomes are small and variable in number because in addition to the stable chromosomes mini-chromosomes are also found. *T. brucei* has only 11 pair larger chromosomes whereas *T. cruzi* and *L. major* have ~28 and 36 pairs, respectively. In addition they have various, undetermined numbers of minichromosomes. The ca. 100 minichromosomes (50 to 150 kb) contain open reading frames for the variable surface glycoproteins (VSG). These sequences are transcribed only when transposed to expression sites in the 0.2 to 6 megabase long 20 maxichromosomes. Since some of the genes may be present in more than single copy in different chromosomes, these organisms may resemble allodiploids. The VSG genes are pseudo-genes, which generate mosaics by ectopic recombination. The genes do not have introns and some of the tandem arrays of genes are transcribed as long polycistronic pre-mRNA. At the 5'-end each primary transcript is capped by a 39-nucleotide, spliced leader

RNA (SLRNA). This cap itself is transcribed as a 139 base sequence but the 100 base sequence is not used in this trans-splicing reaction. The *Trypanosomas* have homologs of the mammalian U2, U4 and U5 small nuclear RNAs in the form of ribonucleoprotein particles (RNP). The mRNAs are polyadenylated. In *T. brucei* there is a family of about 1,000 genes involved in the recurring production of a great repertory of *variant antigen type* (VAT). At each flare-up of division of the parasite, it switches on the production of a different type of antigen (serodeme). The more than million molecules of antigens on the surface of its cells are the phosphatidylinositol-anchored (about 60 kDa) *variable surface glycoproteins* (VSG). These proteins are linked to the membrane by glycosylphosphatidyl inositol (GPI) anchors. Analogs of these proteins may be used for therapeutic purposes (Smith TK et al 2004 EMBO J 23:4701). All the different VSGs have at least one N-linked oligosaccharide and several cysteine residues near the N-end, and some similarities within the 50–100 amino acids at the C-terminus. Because of the rapid switches in production to new antigens, the vertebrate cell's immunological surveillance system cannot adapt rapidly enough to contain the infection. In chronic infections 50–100 different antigens may be produced. Although a particular *Trypanosoma* has only 1/million or less chance per cell division to switch to the production of a different antigen yet because of their immense number, the parasite has a good chance to escape the immune system of the mammalian host. At any one time only one of the VSG genes is expressed in the protozoan. The switching is not a direct response to the host antibody rather that acts

Figure T120. Clusters of orthologous genes

Figure T121. Trypanosoma

only as a selecting mechanism. The switching of transcription may require a shut-off of a gene or a gene conversion type process takes place. The expressed surface antigen gene, the so-called *expression-linked copy* (ELC), is always located in the telomeric regions of the chromosomes. Its promoter is located, however, 50 kbp upstream. In addition, non-VSG genes are also located in the expression region; these are called *expression site associated genes* (ESAG). The expression of these basic, silent genes requires a transposition into the activation region, in a manner similar to the mating type switching in yeast. The switching apparently depends on expression-linked copies (ELC) of the mini exon dependent transcription into 140-base long eukaryotic type mRNA (called also medRNA). Because of this effective switching, there are serious problems in developing vaccines against the *Trypanosomas*. *Trypanosomas* may also display genetic recombination, duplications, deletions and uniparental inheritance mediated by the kinetoplast (Gaunt MW et al 2003 Nature [Lond] 421:936). *Trypanosomas* practice RNA editing by a high molecular mass RNP complex, which contains a 42 kDa protein that recognizes both dsDNA, dsRNA but not the DNA/RNA hybrid molecules. This protein is an endo- and exoribonuclease and functions in also in the mitochondria (Brecht M et al 2005 Mol Cell 17:621). Mutants can be produced that turn on simultaneously more than one type surface glycoproteins. *Trypanosomas* take up transferrin (a β -globulin) from the host cells through about 20 homo- or heterodimeric transferrin receptors, which are activated alternatively just as the VSG genes. The different transferrin receptors make possible for the parasite to adapt to different hosts. The TbAT1 nucleoside transporter confers melaminophenyl arsenical susceptibility whereas defects in TbAT1 render the cells resistant to the trypanocide. ▶kinetosome, ▶*Leishmania*, ▶mating type determination in yeast, ▶flagellar antigen, ▶intron, ▶transporters, ▶RNA editing, ▶Chagas disease, ▶Apolipoproteins; Coppens I, Courtoy PJ 2000 Annu Rev Microbiol 54:129; Navarro M, Gull K 2001 Nature [Lond] 414:759; Spadilero B et al 2002 J Cellular Biochem 85:798; Beverly SM 2003 Nature Rev Genet 4:11; *T. cruzi* sequenced genome: El-Sayed NM et al 2005 Science 309:409; *T. brucei* genome sequence: Berriman M et al 2005 Science 309:416, *T. cruzi* proteome: Atwood JA III et al 2005 Science 309:473; <http://www.tigr.org/tdb/tgi.shtml>; *T. cruzi* database: <http://tcruzidb.org/>.

Tryphine (pollenkitt): Lipids and proteins filling the depressions of the pollen surface.

Trypomastigote: ▶*Trypanosoma*

Trypsin: A proteolytic enzyme synthesized as an enzymatically inactive zymogen, trypsinogen that is activated by proteolytic cleavage. The 6,000 Mr pancreatic trypsin inhibitor inactivates it. Trypsin specifically cleaves polypeptides at the carbonyl sides of Lys and Arg. Ser 195 and His 57 are at its active site.

Trypsinogen Deficiency (TRY1): is a 7q22-ter recessive hypoproteinemia and insufficient amino acid level. It is very similar to enterokinase deficiency. ▶enterokinase deficiency

Tryptases: in the form of heparin-stabilized tetramers function similarly to trypsin-like serine proteases mainly in the mast cells. ▶mast cell, ▶trypsin, ▶heparin

Tryptic Peptides: The products of digestion of a protein by trypsin. ▶trypsin

Tryptophan: Is an essential aromatic amino acid (MW 204.22) (see Fig. T122), soluble in dilute alkali, insoluble in acids and it is degraded when heated in acids. Its biosynthetic pathway (*with enzymes involved in parenthesis*): Chorismate- > (anthranilate synthase) - > Anthranilate - > (anthranilate-phosphoribosyltransferase) - > N-(5'-Phosphoribosyl)-anthranilate - > (N-(5'-phosphoribosyl)-anthranilate isomerase) - > Enol-1-o-carboxyphenylamino-1-deoxyribose phosphate - > (indole-3-glycerol phosphate synthase) - > Indole-3-glycerol phosphate - > Indole - > (tryptophan synthase) - > Tryptophan. In *E. coli* the first two enzymes shown constitute a single anthranilate synthase complex. Tryptophan is converted to formylkynurenine by *tryptophan dioxygenase* (tryptophan pyrrolase). Through the action of an *aminotransferase* tryptophan gives rise to indole-3-pyruvate which after *decarboxylation* forms indole-3-acetic acid, one of the most important plant hormone (auxin). Tryptophan and phenylalanine contribute to the formation of lignins, tannins, alkaloids (morphine), cinnamon oil, cloves, vanilla, nutmeg, etc., flavors. ▶chorismate, ▶tyrosine, ▶phenylalanine, ▶melanin, ▶plant hormones, ▶pigments in animals, ▶Hartnup disease, ▶attenuator, ▶tryptophan operon, ▶fragrances

Figure T122. Tryptophan

Tryptophan Operon: Contains five structural genes, in *E. coli* they have been mapped (at 27 min) in exactly

Figure T123. Part of the bacterial trp operon

the same order as their sequence of action in the biosynthetic path (► [tryptophan](#)). This operon has a principal promoter and a secondary low-efficiency one. Between the operator and the proximal gene there is a 162 bp leader sequence (*trpL*) including an attenuator site *a*. (► [temperature sensitive controlling sequences of transcription](#)). When there is sufficient amount of tryptophan in the cell and all the tRNA^{Trp} are charged with the amino acids, transcription of the leader sequence stops at base 140. Thus, synthesis of the specific mRNA temporarily ceases when there is no immediate need for tryptophan (see Fig. [T123](#)).

The site of attenuation (*a*) is within the *trpL* (tryptophan leader) sequences. Before attenuation becomes effective, the RNA polymerase pauses at the *tp* site in the *trpL* (►attenuation). Two main mechanisms, repression and attenuation regulate expression of this operon. Repression prevents the initiation of transcription. The repressor is transcribed from the *trpR* gene (located at 100 min) and the tRNA^{Trp} is coded by gene *trpT* (84 min) whereas the aminoacylation of this tRNA is determined by gene *trpS* (74 min). The product of *trpR* is an aporepressor, i.e., it becomes active only when combined with tryptophan its corepressor (see tryptophan repressor).

The primary sequence of the leader sequence is as shown below (the underlined sequences indicate ribosome binding, tryptophan codons and critical codons in outline); see above. The tryptophan repressor alone may reduce transcription by a factor of 70 and attenuation may decrease it 8 to 10 fold but by the combination of these two controls transcription may be reduced by 8×70 (=560) or 10×70 (=700) fold. In *Rhodobacterium sphaeroides* the tryptophan operon is shared between the two chromosomes of this bacterium.

Bacillus subtilis regulates seven genes of tryptophan biosynthesis; six of them (*TrpEDCFBA*) are clustered within a 12-gene aromatic supraoperon. The seventh gene (*TrpG*) is unlinked and it is in the folate operon. TRAP regulates by attenuation as it binds to a specific site in leader sequence of the *trp* operon and facilitates a terminator formation of the RNA transcript. In addition, TRAP binds to the ribosome-binding sequence in the *trpG* mRNA and thus inhibits translation. An anti-TRAP (AT) protein signals to the tRNA^{Trp} and then it is not charged with tryptophan.

The uncharged tRNA induces the synthesis of AT. Linking AT to TRAP prevents TRAP binding to the RNA. As a consequence tryptophan biosynthesis is promoted (Valbuzzi A, Yanofsky C 2001 Science 293:2057; Gutierrez-Preciado A et al 2005 Trends Genet 21:432).

In *Neurospora* there are also 5 distinct genetic loci controlling tryptophan biosynthesis. These genes are derepressed coordinately with histidine, arginine and lysine loci and this phenomenon is called *cross-pathway regulation*. Humans do not have tryptophan synthetic genes and depend on it (essential amino acid) in the food. ▶tryptophan, ▶helix-turn-helix, ▶lac operon, ▶repressor, ▶tryptophan repressor, ▶essential amino acids, ▶TRAP, ▶antitermination, ▶attenuation; Yanofsky C 1981 Nature [Lond] 289:271; *Bacillus subtilis*: Gollnick P et al 2005 Annu Rev Genet 39:47.

Tryptophan Repressor: Consists of a repressor protein (using a helix-turn-helix motif) for binding to the operator site of the tryptophan operon and becomes active only when it is associated also with tryptophan. Actually the binding of tryptophan to the repressor protein facilitates the more intense binding of the complex due to a conformational change of the repressor protein. In prokaryotes besides the repressor attenuation is another regulatory mechanism. *E. coli* and *Bacillus subtilis* use somewhat different mechanisms of control. In *E. coli* tryptophan activates a repressor, which binds to the promoter-operator region and inhibits the initiation of transcription. In *B. subtilis* tryptophan activates the RNA-binding protein TRAP. TRA bound to the leader sequences terminates transcription. In *E. coli* uncharged tRNA^{Trp} accumulation stalls when tries to translate the two Trp codons in the leader-peptide coding region. This causes transcription termination. In contrast in *B. subtilis* uncharged tRNA^{Trp} actually activates transcription and translation of this operon. The antitermination protein AT then inhibits TRAP, activated by tryptophan. ▶negative control, ▶tryptophan operon, ▶attenuator region, ▶Lac operon, ▶positive control, ▶arabinose operon, ▶helix-turn-helix motif, ▶conformation; Khodursky AB et al 2000 Proc Natl Acad Sci USA 97:12170; Yanofsky C 2004 Trends Genet 20:367.

Tryptophan Zipper: is a structural motif that can stabilize the hairpin structure of short peptide chains of 12 to 16 amino acids with the aid of cross-strand pairs of indole rings. It does not require metal or disulphide links.

Tryptophanase (*tna*): is a bacterial operon including major genes A, B and a permease with a 319 bp leader encoded (by *tnaC*) preceding gene *tnaA*. It degrades L-tryptophan to indole, pyruvate and ammonia. Tryptophan regulates it by induction and antitermination. ▶ [induction](#), ▶ [antitermination](#); Gong F et al 2001 Proc Natl Acad Sci USA 98:8997.

Tryptophanyl tRNA Synthase (WARS): charges tRNA^{Trp} by the amino acid tryptophan. The gene WARS is in human chromosome 14. ▶ [aminoacyl-tRNA synthetase](#)

ts: indicates temperature-sensitivity of an allele. ▶ [temperature-sensitive mutation](#)

T_S: ▶ [T cell](#)

Tsarevitch Alexis: great-grandson of Queen Victoria who inherited her new mutation causing classic hemophilia. ▶ [hemophilias](#), ▶ [Queen Victoria](#)

tsBN2: is a temperature-sensitive baby hamster kidney (BHK) cell line. ▶ [hamster](#)

TSC: is a reduced representation shotgun sequencing data set. ▶ [shotgun sequencing](#)

TSE (transmissible spongiform encephalopathy): ▶ [encephalopathy](#), ▶ [prion](#)

Tse-Tse Fly: African fly of the genus *Glossina*, host of the parasitic *Trypanosomas*, causing sleeping sickness, a disease characterized by relapsing fever, enlargement of the lymph glands, anemia, severe emaciation and eventually death in humans and domestic animals. ▶ [Trypanosomas](#); Akman L et al 2002 Nature Genet 32:402.

TSG (tumor susceptibility gene): Acts as transcriptional cofactor and also as a nuclear hormone receptor-mediated transactivation. TSG101 protein regulates cell growth and division, MDM2 protein and affects ubiquitination. It controls also epidermal growth factor receptor trafficking by interacting with the endosomal transport. There is ~94% homology between the mouse and the human proteins. ▶ [MDM2](#), ▶ [ubiquitin](#), ▶ [EGFR](#), ▶ [endocytosis](#); Teh BT et al 1999 Anticancer Res 19(6A):4715; Lu Q et al 2003 Proc Natl Acad Sci USA 100:7626.

TSHB: thyroid-stimulating hormone, thyrotropin. ▶ [animal hormones](#)

Tsix: ▶ [Xist](#)

Tsr: Bacterial transducer protein recognizing serine as an attractant and leucine as a repellent. ▶ [transducer proteins](#)

TSS: Transcription start site. (See <http://dbtss.hgc.jp/>).

T-Strand: A single-stranded intermediate of the T-DNA that is transferred from the Ti plasmid of *Agrobacterium* to the plant nucleus through the nuclear pores under the guidance of a virulence gene-encoded protein which is covalently attached to its 5'-end. ▶ [transformation](#), ▶ [T-DNA](#), ▶ [Ti plasmid](#)

tTA (tetracycline transactivator protein): is a fusion protein of the *tet* (tetracycline) repressor of *E. coli* and the transcriptional activation domain VP16 of herpes simplex virus. This system is generally driven by the *tetP* promoter which is actually a minimal immediate early cytomegalovirus (CMVIE) promoter, preceded by 7 copies of *tetO*, the tetracycline resistance operator of transposon 10 (*Tn10*). In the presence of tetracycline, this system is expressed at very low level and by removal of tetracycline the gene(s) under its control (e.g., luciferase, β -galactosidase) may be expressed at three orders of magnitude higher level. The system can be used also under the control of other promoters that suit best for regulating the expression pattern of the gene of interest. ▶ [rtTA](#), ▶ [tetracycline](#), ▶ [split-hybrid system](#); Gossen M, Bujard H 1995 Science 268:1766.

t-Test: is used for the estimation of the statistical significance of the difference(s) between means. The *t* value is the ratio of the observed difference to the corresponding standard error: $t = (\bar{x} - m) / (s / \sqrt{n})$ where \bar{x} and *m* are the two means, *n* = population size, *s* = standard deviation. More commonly the significance of the difference between two means is calculated as $t = \frac{m_1 - m_2}{\sqrt{[e_1]^2 - [e_2]^2}}$ where *m*₁ and *m*₂ are the two means (\bar{x}) and *e*₁ *e*₂ are the standard errors of the two means determined as $e = \frac{s}{\sqrt{n}}$ and $s = \sqrt{V}$ where $V = \text{variance} = \frac{\sum[(x - \bar{x})^2]}{n-1}$. When the *t* value is available the probability of the difference is determined with the aid of a “t table”. ▶ [Student's t distribution](#)

TTKs: are tubulin-associated kinases. ▶ [tubulin](#)

TTP (tris-tetrapolin): cDNA shares 102 amino acid sequences in its product with TIS11 (insulin and serum-responsive transcription factor). ▶ [TIS11](#), ▶ [insulin](#), ▶ [serum response element](#), ▶ [transcription factors](#)

T-Tropic: The T lymphocyte is targeted (e.g., by a virus).

TU: Protein elongation factor (EF-TU) in prokaryotes binds aminoacyl-tRNA to the ribosomal A (acceptor) site. It is a guanine nucleotide-binding RAS-like protein. EF-TU.GTP, ►aminoacyl-tRNA, ►ribosome, ►protein synthesis, ►RAS; Zvereva MI et al 2001 J Biol Chem 276:47702.

Tubal Ligation: Surgical fertility control by constricting of the Fallopian tube, usually by placing a plastic ring on it. ►sterilization humans, ►salpingectomy

Tube Nucleus: It is in the vegetative cell at the tip of the growing pollen tube. It has only physiological and no genetic role because it does not enter the embryosac. ►gametophyte

Tuber: An underground enlarged stem, specialized for food storage, e.g., in potato.

Tubercidine (7-deazadenosine): ►deazanucleotides

Tuberculosis: ►mycobacteria

Tuberous Sclerosis: ►epiloia

Tuboplasty: Surgical repair of a defect on an internal tube such as the Fallopian tube.

Tubulins: Globular polypeptides of α and β subunits (50 kDa, each with about 40% homology and very similar in structure [β sheets surrounded by α helices]) are G-proteins concerned with signal transduction of nerve cells and are components of microtubules such as the spindle fibers and the cytoskeleton. Mutations in α -tubulin cause abnormal migration of neurons in mice and lissencephaly in humans (Keays DA et al 2007 Cell 128:45). Both subunits can bind one guanine nucleotide, which is an exchange cable on the β but not on the α binding site. The folding of the tubulins requires cytosolic chaperonins, cofactors A, C, D and E, ATP and GTP. The bacterial plastid septation protein FtsZ filamenting temperature-sensitive septal peptidoglycan (Z ring) displays structures similar to tubulins and participates in the septation of the cell (see Fig. T124). FtsZ may have a GGGTGTG motif and has GTPase activity. FtsZ3 with the GGGAGTG motif has no and FtsZ84 with the AGGTGTG sequence have reduced GTPase activity. FtsZ recruits then addition cell division proteins. In the spore-forming bacteria (*B. subtilis*) initially two Z rings are formed, one at both poles but only one is activated as the genetic material passes to the spore. In the chloroplasts a nuclear encoded ftsZ protein and

dynamain function in fission (Yoshida Y et al 2006 Science 313:1435). The mitochondria apparently do not need ftsZ. ►spindle, ►cytoskeleton, ►chaperonins, ►peptidoglycan, ►septum, ►GTPase, ►chloroplasts, ►mitochondria, ►FtsZ, ►lissencephaly; Oakley BR 2000 Trends Cell Biol 10:537; Thanbichler M, Shapiro L 2006 Cell 126:147; Z ring regulation: Lutkenhaus J 2007 Annu Rev Biochem 76:539.

Tudor (*tud*, 2–97): *Drosophila* gene locus involved in embryonic development. ►TRF1

Tudor-SN: Protein containing the Tudor protein of *Drosophila* and five staphylococcal nuclease domains. It is a component of the RISC silencer complex. ►RISC; Maurer-Stroh S et al 2003 Trends Biochem Sci 28:69.

TUF (transcripts of unknown function): The number of RNA transcripts (from intergenic regions, introns and antisense DNA strands) far exceeds the number of protein-coding mRNAs (Johnson JM et al 2005 Trends Genet 21:903; Willingham AT, Gingeras TR 2006 Cell 125:1215). They are parts of the operational system of the genome. ►non-coding RNA, ►antisense RNA, ►RNAi, ►microRNA

Tukey's Test: is an analysis of variance test for determining whether there is a significant difference between three or more group means, two comparisons made at a time. This is a non-additivity test.

$$S_{AB} = \frac{[\sum_{i=1}^r \sum_{j=1}^c \{y_{ij}(\bar{y}_i - \bar{y}_{..})(\bar{y}_j - \bar{y}_{..})\}]^2}{S_A S_B}$$

Where the sum of squares is S_{AB} , r is the number of rows, c = number of columns, y_{ij} = observations in the i^{th} cell, \bar{y}_i = mean of the i th row, $\bar{y}_{..j}$ = mean of the j th column and $\bar{y}_{..}$ = mean of all observations. (See Tukey JW 1949 Biometrics 5:232; ►analysis of variance).

Tularemia: is an extremely dangerous infection causing sudden fever, weakness, bodyache in humans and animals. It is caused by as few as 10 cells of the bacterium *Francisella tularensis* transmitted by arthropod vectors. It may also spread by airborne dust. Without antibiotic treatment the mortality is 5–30%. Currently no vaccine is available. The sequenced genome of the bacterium is 1,892,819 bp. ►biological warfare, ►inflammasome; Larsson P et al 2005 Nature Genet 37:153.

Tulip Mania: ►symbionts hereditary, ►tulips broken

Tulips, Broken: Variegation caused by infection with the tulip-breaking virus. Floriculturists value the plants displaying this sectoring. ►tulip mania, ►broken tulips

Figure T124. Septation by bacterial Z ring

Tulips-PCR (touch up and loop incorporated primers PCR): See Ailenberg M, Silverman M 1999 *Bio-techniques* 29:1018.

Tumbling: results when the bacterial flagella (singular: flagellum) rotate clockwise.

TU/ml: Transforming unit per mL, i.e., the number of cells expressing a transgene. ▶[transgene](#), ▶[transformation genetic](#)

Tumor: An abnormal clump of cells originated by benign or malignant growth. Malignant tumors may be invasive and show metastasis, common in many types of cancer. Mutant genes, chromosome breakage and viral infections altering the normal regulation of cell proliferation may cause it (see Fig. T125). Tumorigenesis is generally a multi-phase process involving activation of cell cycle promoting genes and inactivation of tumor suppressors. Active MAPKK may stimulate tumorigenesis if transfected into mouse cells. The type of the tumor is different in different cancers and even within a single cancer may vary a great deal because of the frequent chromosomal breakage and other mutations as a consequence of cancerous growth. The origin and maintenance of the tumorous condition requires the emergence of special tumor stem cells brought about by asymmetric division of normal somatic cells (Gonzalez C 2007 *Nature Rev Genet* 8:462). Their characterization, using molecular markers may be facilitated by microarray analysis of the biopsies. Plant tumorous growth is often called callus that is never metastatic although the crown gall tumors of plants may be spread by new foci of infection of the inciting bacterium, *Agrobacterium tumefaciens*. Plant viruses and higher concentrations of phytohormones may also cause tumors. ▶[oncogenes](#), ▶[cancer](#), ▶[SV40](#), ▶[adenoviruses](#), ▶[Agrobacterium](#), ▶[genetic tumors](#), ▶[tumor in situ](#), ▶[cancer](#), ▶[MAPKK](#), ▶[habituation](#), ▶[CATRI](#), ▶[microarray hybridization](#), ▶[cancer gene therapy](#), ▶[RAS](#), ▶[PIK](#), ▶[TOR](#); Shaw RJ, Cantley LC 2006 *Nature [Lond]* 441:425.

Figure T125. General growth regulatory pathways

Tumor Antigens: are MHC-associated peptides recognized by CTLs as tumor antigens. The MHC class I tumor peptides are also called CTL epitopes. Mutant chaperone can convert a glycosyltransferase into a tumor-specific glycopeptidic neo-epitope (Schietinger A et al 2006 *Science* 314:304). ▶[MHC](#), ▶[CTL](#), ▶[epitope](#), ▶[glycosyltransferases](#), ▶[dendritic cell vaccine](#), ▶[tumor vaccination](#), ▶[cancer](#)

Tumor, In Situ: Dormant, tiny clumps of tumor cells, usually revealed by autopsies of breast, prostate and thyroid glands. The microscopic cells may never develop into cancer because the lack of appropriate blood supply (angiogenesis). The in situ tumors may originate by genetic instability but unless they succeed in recruiting new blood vessels, they are unable to proliferate into neoplasias. There is a balance between the angiogenic growth factors such as FGF, VEGF, IL-8, and PDGF and the angiogenic inhibitors of the body (thrombospondin, canstatin [24 kDa human basement membrane-derived antiangiogenesis protein], tumstatin [cleavage fragment of the α -3-chain of collagen type IV that prevents blood circulation], endostatin, angiostatin, interferon α/β . Genetical and environmental factors control the balance among the pro- and anti-angiogenic factors. (See terms at corresponding entries, ▶[tumor](#)).

Tumor Infiltrating Lymphocytes (TIL): seek up tumors. TIL are isolated from solid tumors and cultured in single-cell suspension in a medium containing interleukin 2 (IL-2). Through genetic engineering they may be equipped with the gene of tumor necrosis factor through transformation by retroviral or other vectors. The transformed cells may selectively kill then cancerous tumor cells. ▶[cancer gene therapy](#), ▶[tumor necrosis factor](#), ▶[retroviral vectors](#), ▶[lymphocytes](#); Smyrk TC et al 2001 *Cancer* 91:2417.

Tumor Necrosis Factor: ▶[TNF](#)

Tumor Necrosis Factor Receptor: ▶[TNFR](#)

Tumor Progression: ▶[evolutionary clock](#)

Tumor Promoter: ▶[phorbol ester](#)

Tumor Suppressor Gene: Its loss, inactivation or mutation (even haploinsufficiency) permits neoplastic growth by deregulation. They most commonly have a role in the cell cycle or in the regulation of RNA polymerase II or III. Also, inhibition of peptide chain elongation may be a mechanism of tumor suppression. (Genes with cytostatic or cytotoxic effects are excluded from this category of tumor suppressors). Actually, the majority of cancer cells display deletions that may indicate the loss of a tumor suppressor gene; for the direct proof further evidence

is required for the loss of a tumor suppressor (see Fig. T126). Animal models are available for many human tumor suppressors (Hakem R, Mak TW 2001 Annu Rev Genet 35:149). Tumor suppressor genes

Figure T126. A tumor suppressor path

are widely scattered in the human genome: p53/TP53 (17p13.1), retinoblastoma (RB1, 13q14.1-q14.2), adenomatous polyposis of colon (APC, 5q21-q22), deleted in colorectal cancer (DCC, 18q21.3), neurofibromatosis (NF1, 17q11.2), von Hippel-Lindau syndrome (VHL, 3p26-p25), Wilms tumor (WT1, 11p13), breast cancer (BRCA1, 17q21), Cyclin-dependent kinase inhibitor CDKN2A, (9p21), patched homolog PTCH (9q22.3), tuberous sclerosis (TSC2, 16p13.3; TSC1, 9q34), etc. Mutation in the polycomb group protein enhancer of zeste homolog (EZH2) may increase its expression and represses the function of many genes that are apparent suppressors of tumorigenesis and thus promotes lethal metastasis of prostate cancer (Varambally S et al 2002 Nature [Lond] 419:624). The methyltransferase Suv39h1 normally methylates histone H3 lysine 9 and may silence growth-promoting genes. By the use of RNAi, tumor suppressor genes can be inactivated and the procedure permits their identification (Westbook TF et al 2005 Cell 121:837; Kolfshoten IG et al 2005 Cell 121:849). Ras transgenic mice carrying intact, X-linked, functional Suv39h1 developed lymphomas only at a median of 305 days. Suv39h1 deficient homozygotes (female) or hemizygotes (male) succumbed to death at a median time of 66 days. The methyltransferase acted as a tumor suppressor by promoting senescence (Braig M et al 2005 Nature [Lond] 436:660). The protein spliceosome factor (PSF) has an RNA and DNA binding domain and can bind to the P450ssc gene, which initiates also the steroidogenic pathway. The retrotransposon VL30 – a multiple element in the mouse genome and also in the human genome – regulates the function of PSF (Song X, Garen A 2005 Proc Natl Acad Sci USA 102:12189) by binding its RNA transcripts to the RNA binding domain (RBD) of PSF. Subsequently PSF is removed from the promoter and the oncogene is transcribed (See diagram redrawn and modified after Desisseroth A 2005 Proc Natl Acad Sci USA

102:12292). ▶cancer, ▶malignant growth, ▶transformation oncogenic, ▶p53, ▶p73, ▶p16, ▶p16^{INK4} p21, ▶retinoblastoma [Rb], ▶ELL, ▶elongin, ▶DPC4, ▶PTEN, ▶PPP2R1B, ▶pol III, ▶tumor suppressor factors, ▶RNAi, ▶polycystic kidney disease, ▶breast cancer, ▶prostate cancer, ▶oncogenes, ▶cell cycle, ▶apoptosis, ▶colorectal cancer, ▶tumor suppressor factors, ▶LOH, ▶oncogenes, ▶immunosuppression, ▶histone deacetylase, ▶gate-keeper genes, ▶caretaker genes, ▶hypermethylation; Robertson GP et al 1999 Mol Cell Biol Res Comm 2:1.

Tumor Suppressor Factors: The development of tumors follows multiple routes yet genes involved in the general control of differentiation, as revealed by studies of *Drosophila* morphogenesis, seem to be involved. Mammalian homologs of *Drosophila hedgehog* (*hh*), sonic hedgehog (SHH), Indian hedgehog (IHH) and desert hedgehog (DHH) seem to be entailed in holoprosencephaly, a developmental anomaly connected to cancer. The receptor of *hedgehog* of *Drosophila* is *smoothed*, and its suppressor is *patched* which may be concerned with the development of basal cell carcinoma and defects in the central nervous and skeletal systems. The *cubitus interruptus* (*ci*) *Drosophila* gene appears to function as an effector of *hh* and similarly to the GLI genes of humans are responsible for a type of brain tumor and for the cephalopolysyndactyly syndrome. The decapentaplegic (*dpp*) *Drosophila* protein bears similarity to the mammalian tumor growth factor (TGF) and to the bone morphogenetic protein 4 (BMP4), causing defects in limb and gut formation. The effector of the mammalian TGF- β receptor (DPC4) involved in pancreatic tumors has its homolog in the *Drosophila mad* gene. The *Drosophila wingless* locus corresponds to the mammalian WNT loci controlling mammary tumors. The *Drosophila zeste-white-3* gene codes for a signal molecule similar to a mammalian glycogen synthase kinase, and the *Drosophila armadillo* gene, encoding β -catenin, is also an oncoprotein, controlling intestinal tumors. Naïve CD4⁺ T cells respond to MHC-II tumor antigenic signal carried by macrophages and along with interferon- γ inhibit tumor cell growth (Corthay A et al 2005 Immunity 22:371). Fe chelators have potent and broad antitumor activity and can overcome resistance to established chemotherapeutics because of their unique mechanism of action (Whitnall M et al 2006 Proc Natl Acad Sci USA 103:14901). (Based to some extent on Dean M 1996 Nature Genetics 14:245, ▶immunological surveillance, ▶Tid50, see terms mentioned in the alphabetical list).

Tumor Susceptibility: May be determined by mutation of some major tumor suppressor (RAS, CyclinD1,

RB, p16, etc.) genes, favorable combination(s) of minor genes may be responsible for the “sporadic” cases of cancer. ▶tumor suppressor gene, ▶onco-genes; for a list of mouse susceptibility loci see Balmain A, Nagase H 1998 Trends Genet 14:139.

Tumor Vaccination: Immunization by increasing the efficiency of tumor-specific antigen presentation or enhancing the activity of tumor-infiltrating T cells. The purpose is to generate antitumor immune reaction. Cancer cells may be ex vivo genetically modified and reintroduced into the body. Introducing into the cancer cells a range of cytokines e.g., IL-12 may enhance T cell response. The T cells of the tumor can be genetically modified to secrete effector molecules to enhance the immune response against the tumor or increase their potentials for binding of tumor antigens. Introduction of the wild type tumor-suppressor genes may also be an option. Transformation by GM-CSF may recruit monocytes/macrophages and APCs by a process called *cross priming*. Some tumors may mask the immunogenic potentials within the cells. In such cases, antisense technologies (against IGF or TGF or IL-10), intrabodies, triple helix formation, and inactivation by the use of ribozymes may help in silencing the endogenous inhibitors. It is also possible to introduce into the tumor activation enzymes that can convert pro-drugs into highly cytotoxic anticancer compounds or transfect the cells with toxin genes.

Because of pleiotropy and protein interactions, the genetic modifications may not always be favorable for goals. Within the same individual, molecular heterogeneity may exist among the cancer cells. Therefore, only multivalent cancer vaccines may achieve relevant goals. Favorable results were obtained in animal models with the combinations of IL-4 + IL-12, co-stimulatory molecules + IL-12, interferon- γ + IL-2, etc. Often, tumor cells have no or very weak antigen-presenting mechanism(s), and do not express the co-stimulatory proteins. Melanoma cells over-produce IL-10, a cytokine that down-regulates the path of CTL formation. The Fas-ligand expressing lymphocytes may be the targets of the up-regulated Fas, produced by tumor cells, especially when exposed to certain types of chemotherapy. As a consequence, the apoptotic process may weaken immunotherapy against cancer. Cancer may involve tumor-specific immunodeficiency but low doses of IL-2, administered over long periods may strengthen the immune system. It is essential that in therapy against cancer the various treatments be effective against cancer cells without attacking the normal cells and balance the antitumor and autoimmune responses. ▶cancer gene therapy, ▶tumor infiltrating lymphocytes, ▶CTL, ▶antigen presentation,

▶immune system, ▶interferon, ▶vaccines, ▶dendritic cell vaccine, ▶cross-priming, ▶GM-CSF, ▶co-stimulator, ▶antisense RNA, ▶intrabody, ▶triple helix formation, ▶ribozyme, ▶IGF, ▶TGF, ▶IL-10, ▶lipids cationic, ▶co-stimulator, ▶LAK, ▶Fas, ▶apoptosis, ▶autoimmune disease, ▶effector cell; Gunzer M, Grabbe S 2001 Crit Rev Immunol 21 (1–3):133; Tada Y et al 2003 Cancer Gene Ther 10:134.

Tumor Viruses: Tumor viruses induce or participate in the formation of tumors (cancer). Their genetic material can be DNA (such as, SV40, adenoviruses, papilloma virus, hepatitis-B virus, Epstein-Barr virus, adenoma virus, herpes virus, pox virus) or RNA (such as the retroviruses causing leukemia, lymphoma, AIDS, Kaposi’s sarcoma, avian leukosis virus, mammary tumor viruses, etc). The DNA viruses can integrate into the mammalian genetic material and activate cell replication by overwhelming the function of the tumor suppressor genes. The genetic material of the DNA tumor virus has no counterpart in the host genetic material. The genetic material of the RNA tumor virus is replicated by reverse transcription and produces a double-stranded DNA counterpart of the genome. The viral RNA is then transcribed from the cellular DNA template. Most of the oncogenes in the cells (c-oncogenes) correspond to the v-oncogenes in the virus. The class I RNA tumor viruses themselves do not induce tumors unless they pick up growth-regulating genes from cell. The class II type RNA viruses do not contain oncogenes and induce cancer only when the proviral DNA integrates in the vicinity of cellular oncogenes (c-oncogenes). ▶SV40, ▶adenovirus, ▶Epstein-Barr virus, ▶papilloma virus, ▶polyoma, ▶Rous sarcoma, ▶retroviruses, ▶oncogenes; Barbanti-Brodano G et al (Eds.) 1995 DNA Tumor Viruses, Plenum, New York; McCance DJ (Ed.) 1998 Human Tumor Viruses. AMS Press, Washington, DC.

Tumor-Associated Antigen: Over-expressed normal self-proteins of cancer cells. They may incite immune reaction by breaking the self-tolerance limit. Examples: oncofetal differentiation, nuclear proteins, such as carcinoembryonic, melanoma-associated proteins, etc. ▶MAGE, ▶HER2

Tumorigenesis: The formation of tumors. It is usually based either on the activation of proto-oncogenes or the inactivation of tumor suppressor genes. The former mechanism generally involves dominant-acting genes, the latter is usually based on recessive loss of function. Before genetic instability, characteristic for cancer or cancer-prone cells appears, an ATR/ATM-regulated DNA damage control system may be activated. Mutations in ATM-Chk2, p53

pathway might allow, however cell proliferation, cell survival, increased chromosomal instability, and eventually progression to cancer (Bartkova J et al 2005 Nature [Lond] 434:864). Fourier-transform infrared spectra (FT-IR) reveal structural modifications at many points in the DNA and marked differences between the primary and metastatic states. ▶cancer, ▶neoplasia, ▶FT-IR, ▶telomerase, ▶tumor suppressor, ▶proto-oncogenes, ▶chromosome breakage, ▶apoptosis, ▶DNA repair, ▶radiation effects, ▶environmental mutagens, ▶carcinogenesis, ▶ATM, ▶ATR, ▶CHK2, ▶p53

Tumorous Hybrids: ▶genetic tumors

Tumor-Specific Antigen: Endogenous tumor cell-surface antigens that can be presented by major histocompatibility molecules to T cells. These antigens are absent from normal cells and are modified in response of viral transformation or genetic or somatic mutations in oncogenes. ▶MHC, ▶T cell, ▶antigen presenting cell

TUNEL ASSAY (terminal deoxytransferase-mediated deoxyuridine nick end-labeling): Tunnel assay uses usually biotin-labeled uridine and a streptavidin or avidin-labeled enzyme, and at the reaction site color develops. ▶biotinylation, ▶terminal nucleotidyl transferase; Maciorowski Z et al 2001 Cytometry 46(3):159; Yamamoto-Fukud T et al 2000 Histochemistry J 32(11):697.

Tunica: The cell layer in the plant apical meristem wrapping the inner corpus. (See Fig. T127).

Figure T127. Tunica

Tunneling: connecting through a structured path. ▶channeling

TUP1: A general suppressor of sugar (and other) metabolism of yeast; its product is a trimeric G-protein. It is similar to AAR1 and AAR2. TUP forms a repressor complex with yeast protein Cyc8, RNA polymerase II, and Srb10. ▶proteins, ▶glucose

effect; Groucho, Tel, SRB, Wu J et al 2001 Mol Cell 7:117.

Tupaia: A family of prosimii. *Tupaia*, 2n = 62; *Tupaia glis*, 2n = 60; *Tupaia montan*, 2n = 68. ▶prosimii

Turbid Plaque: ▶plaque

Turbidity: Turbidity is commonly used for measuring total cell numbers in liquid cultures as long as the cell density is not excessive. It is measured as optical density (OD) = x/l , where x = cell density and l = the light path in the cuvette of the spectrophotometer. Turbidity is expressed also as $\log(I_0/I)$ where I_0 = incident light, I = transmitted light (at e.g., 550 nm wavelength). The number of viable cells is determined by plating. ▶plating efficiency, ▶cell growth

Turcot Syndrome (9p22, 54q21-q22, 3p21.3): An autosomal recessive malignant tumor of the central nervous system (glioma), associated with polyposis. Defects in the mismatch repair system predispose for this tumor. ▶polyposis adenomatous, ▶Gardner syndrome, ▶PMS1, ▶mismatch repair

Turgid: Expanded because of water uptake.

Turgor: Intracellular pressure caused by water absorption.

Turing, Alan (1912–1954): A mathematician, philosopher, and pioneer in computing and bioinformatics who intended to develop machines and software that work like the human brain.

Turkey: *Meleagris gallopavo*, 2n ≈ 80.

Turner's Rule: Turner's rule deals with the thermodynamics of helix formation of ribonucleotides, which also involves mismatches (Freier SM et al 1986 Biochemistry 25:3209).

Turner Syndrome: Based on an X0 chromosomal constitution in some female mammals. Its incidence in humans is ≈ 0.0003 but the frequency in abortuses may be 0.01 to 0.02. The missing short arm is critical for the Turner symptoms. Turner females usually have short stature, webbed skin on a broad neck, under-developed genitalia and sterility, heart problems, proclivity to kidney disease, diabetes, and hypertension but are generally of normal or near normal intelligence (see Fig. T128). Mathematical abilities are generally reduced (dyscalculia). The retention of the paternal X usually results in better cognitive abilities (imprinting).

Figure T128. Turner syndrome females of different ages. With three doses of the long arm but only one short arm of the X chromosome. Despite the variations in appearance the similarities of the unrelated individuals is obvious. (Courtesy of Lindsten J et al 1963 *Ann Hum Genet* 26:383)

In some instances they are also fertile; most of these cases are probably XO/XX mosaics. In a study among 410 Danish women with Turner syndrome, only the 45, X/46,XX or 46,XX with structural abnormality of one of the X-chromosomes were found to give birth after spontaneous pregnancy. After egg donation, some Turner patients can deliver children although there may be a higher chance for chromosomal anomalies among the offspring (Birkabaek N et al 2002 *Clinical Genet* 61:35). The symptoms are similar even when only the one of the short arms of one of the X-chromosomes is missing. The single X chromosome is maternal in 75% of the cases. The underlying mechanism is puzzling because males normally have a single X, while even in females one of the X-chromosomes is inactive, except during oogenesis and the first few weeks of embryogenesis. The majority of studied female animals with single X (pigs, cattle, horse) are abnormal but the XO female mice appears rather normal and fertile. In *Drosophila*, the XO individuals are sterile males. In Turner syndrome, the most critical is the loss of the distal (pseudoautosomal) part of the short arm of the X chromosome (see Fig. T129). Some of the human developmental difficulties may be normalized by estrogen treatment. Artificial insemination or intra-uterine implantation may permit reproduction. About 15% of the X chromosomes in Turner patients are dicentric. ▶[trisomy](#), ▶[sex determination](#), ▶[sex chromosomal anomalies in humans](#), ▶[human chromosome map](#), ▶[prenatal diagnosis](#), ▶[MSAFP](#),

Turnip (*Brassica campestris*): A polymorphic species with chromosome number $2n = 2x = 20$, *Brassica napus* is $2n = 4x = 38$, AACC genomes. ▶[Brassica oleracea](#)

Turnip Crinkle Virus (TCV): A plant RNA virus related to the Tomato Bushy Stunt Virus.

Turnover: The depletion-repletion cycle of molecules or cells. The age of cells in the human body is not easy to determine. Nuclear weapon testing after World War II increased the ^{14}C level in the atmosphere but after 1963 an exponential decrease followed international agreements of testing. The level of ^{14}C in the DNA paralleled this trend and thus it became possible to infer the age of cells, i.e., the time when the DNA and the cell replicated. Occipital neurons in the adult human brain were as old as the individual, indicating that postnatal neurogenesis did not take place in this region. In contrast, non-neural cells were replaced by cell division. This type of procedure makes possible the study of cell turnover that may be important for normal physiology and pathology (Spalding KL et al 2005 *Cell* 122:133).

Turnover Number: The number of times an enzyme acts on a molecule in a unit of time at saturation.

Turnover Rate: The pace of decay and replacement of a molecule.

Tus Gene Products: Proteins that sense the *Ter* (transcription termination) sequence signals in DNA replication in *E. coli*. ▶[DNA replication](#), ▶[replication bidirectional](#), ▶[prokaryotes](#), ▶[RTP](#); Henderson TA et al 2001 *Mol Genet Genomics* 265:941.

TUSC (Trait Utility System for Corn): TUSC generates insertional mutations in maize with the aid of transposable elements like *Mutator*. ▶[insertional mutation](#), ▶[Mu](#)

Tv/Rcas Vector: The Rous sarcoma avian virus proviral vector (maximum carrying capacity 2.5 kb) first mediates in vitro the production the avian leukosis virus (AVL) coat protein. The protein is required for the recognition of the avian retroviral receptor (tv-a), transfected into mouse cells. The replication competent virus thus can produce high titer in the mouse cells infected and can be injected into mice. ▶[Rous sarcoma](#), ▶[retroviruses](#); Fisher G et al 1999 *Oncogene* 18:5253.

Tweak (Apo3-L, 17p13.3, TNF-related weak inducer of apoptosis): A TNF ligand with similarity to CD120

and CD95. The related motif of its mouse homolog displays greater similarity. It is a factor in the Klippel-Trenauney syndrome. ▶TNF, ▶CD95, ▶CD120, ▶Klippel-Trenauney syndrome; Kaplan MJ et al 2000 J Immunol 164:2997; Schneider P et al 1999 Eur J Immunol 29:1785.

Tween 20 (polyoxyethylene sorbitan, monolaurate): An anionic biological detergent with about 50% lauric acid; the rest comprises of myristic, palmitic, and stearic acids.

Twigdam: Technical Working Group on DNA Analysis Methods. It is concerned with forensic application of DNA analytical and statistical techniques ▶DNA fingerprinting

Twin Hybrids: ▶complex heterozygotes

Twin Meiosis: Twin meiosis may occur in diploid *Schizosaccharomyces* when after copulation the two nuclei undergo separate meioses.

Twin Spots: Twin spots are visible if (mitotic) somatic crossing over takes place between appropriately marked chromosomes, or may be caused by nondisjunction (see Fig. T130). ▶mitotic crossing over; Rédei GP, Sandhu SS 1988 Mutation Res 201:337.

twine: *Drosophila* homolog of *Cdc25* meiosis-specific gene. ▶cdc25, ▶azoospermia

T

Twinning: The phenomenon of developing two (or multiple) zygotes from a single impregnation in usually uniparous mammals. The frequency of twins is different in various ethnic groups. Among Nigerians it may be as high as 4.5% and in some South American and Far-East populations it may be as low as 0.8%. In the USA, its frequency among whites was found to be about 0.89 to 0.94% and among blacks, 1.37%, before the widespread use of fertility promoting drugs.

Following in vitro fertilization about half of the births are multiple. Between 1980 and 1997, twinning increased by 52% and the frequency of triplets and higher order gestations has quadrupled in the USA. Multiple births involve considerable medical risk to the babies and mother. The gestation time is

frequently reduced by four weeks for twins, by six weeks for triplets and by 10 weeks for quadruplets. The mortality rate (~16%) and developmental anomalies are higher. The lower birth weight involves the risk for physical and mental handicaps. "Multi-fetal reduction" during the first 9–12 weeks of gestation by injecting potassium chloride into one or more of the fetuses may alleviate medical problems but may cause the loss of the pregnancy entirely. The procedure also involves serious ethical dilemmas, religious conflicts, psychological and other trauma (Elster NJD 2000 FertilSteril 74:617.) Twins are either *monozygotic* (identical) or *dizygotic* (fraternal). The former are derived from a single fertilized egg and the latter develop from two separate eggs fertilized by different sperms. In the overwhelming majority of cases, monozygotic twins are genetically identical whereas the dizygotic twins are comparable to any other siblings. It is possible that some dizygotic twins display higher similarity if one unfertilized egg gave rise to two blastomeres and two separate sperms fertilized each. Another possibility is if one of the polar bodies (identical to the egg) becomes an egg due to a developmental mishap. The identity of monozygotic twins may be somewhat reduced due to epigenetic changes (epigenetic shift).

In an unusual case of twins (Souter VL et al 2007 Human Genet 121:179), both had a 46, XX/46,XY chromosome complement in peripheral lymphocytes, skin fibroblasts, and gonadal biopsies. The proportion of XX to XY cells varied between the twins and their tissues. The cells were chimeric, and shared 100% of maternal alleles and approximately 50% of paternal alleles in the DNA analysis of skin fibroblasts. Possibly, earlier the egg divided and each was fertilized by a different sperm or a single egg was fertilized by two spermatozoa resulting in a triploid zygote, which later split and lost one or another set of chromosomes and became cytologically euploid (see Fig. T131).

Although after birth monozygotic twins appear entirely identical, during development, due to differences of methylation and histone acetylation, phenotypic differences may arise (see Fig. T132) (Fraga MF et al 2005 Proc Natl Acad Sci USA 102:10604). In a unique incident, a monozygotic twin suffering from ovarian failure was able to conceive and deliver apparently healthy offspring, after transfer of ovarian cortical tissue from her healthy sister. (Sherman J et al 2005 New England J Med 353:58).

The frequency of twinning has a genetically determined component as the studies of various ethnic groups indicate. There are indications that the genetic component plays a greater role in dizygotic twin birth than in monozygotic births.

Figure T131. Human twins can be either mono- or dizygotic and the two conditions can be distinguished also on anatomical basis of the developing fetus. Monozygotic twins are surrounded by a common chorion (c and d) or even by a single amnion (D). (A) and (B) are most likely dizygotic. (Modified after Stern, C. Principles of Human Genetics, Freeman, San Francisco)

Figure T132. Monozygotic (1st and 3rd) and dizygotic twins (2nd and 4th)

Monozygotic twins are expected to be of the same sex. Exceptionally, one of the XY male twin embryos may lose the Y chromosome and develop into an XO (possibly mosaic) female. The XO human cells develop into Turner syndrome females, unlike in *Drosophila* where XO individuals are sterile males. Non-concordance for sex in identical twins may be the result of mutation in autosomal or X-chromosomal sex-reversal genes. Sometimes it is difficult to distinguish between identical and non-identical twins on the basis of phenotypic similarities. DNA fingerprinting may resolve the problem. Dermato-glyphics may not always be conclusive due to developmental differences in digital, palmar, or plantar (sole) ridge counts in monozygotic twins. Mono- and dizygotic twins provide useful tools for the study of inheritance of polygenically determined human traits. Among women of families with dizygotic twins, the rate of twinning is about double that of the general population and may be attributed to hereditary hormone levels. The inheritance of twinning through the male parent is lower than through the female. Monozygotic twinning may not or may have very low genetic component. There are statistical methods for the discrimination between identical (MZ) and non-identical (DZ) twins based on concordance of alleles (DNA or any other type).

Maynard Smith and Penrose (Ann. Human Genet. 19:273) worked out the following formula for the probability of concordance for DZ

$$\text{twins: } P = \left(1 + 2 \sum_{i=1}^n p_i^2 + 2 \left[\sum_{i=1}^n p_i^2 \right]^2 - \sum_{i=1}^n p_i^4 \right) / 4 ,$$

where i stands for the phenotype of the markers, n = number of alleles, p_i = allelic frequencies calculated on the basis of the binomial distribution for the various types of matings. ▶DNA fingerprinting, ▶fingerprints, ▶forensic genetics, ▶heritability estimation in humans, ▶freemartin, ▶superfetation, ▶multipaternal litter, ▶multiparous, ▶zygosis, ▶concordance, ▶discordance, ▶co-twin, ▶quadruplex, ▶ovulation ovary, ▶SRY, ▶sex reversal; Jones H, Schnorr JA 2001 Fertil Steril 75:11; Boomsma D et al 2002 Nature Rev Genet 3:972; epigenetics of twins: Petronis A 2006 Trends Genet 22:347.

Twins: ▶twinning

Twinscan: A gene-finder program (similar to GENSCAN) suitable to analyze homologous sequences and genes of two related genomes. ▶GENSCAN, ▶SGP-1; Korf I et al 2001 Bioinformatics 17, Suppl. 1:S40; Wei C et al 2005 Genome Res 15:577.

Twintron: ▶intron group III

Twist (*Drosophila* gene *twi*, 2–100): The lethal embryo is twisted in the egg case as the germ cell layers are defective. Mutation in the human homolog is responsible for the Saethre-Chotzen syndrome. Twist mediates also metastasis by reducing e-cadherin-controlled cell adhesion (Yang J et al 2004 Cell 117:927). ▶cadherins, ▶metastasis, ▶Chotzen syndrome

Twisting Number: The twisting number characterizes DNA supercoiling by indicating the number of contortions (writhing) and the number of twists, i.e., the number of nucleotides divided by the number of nucleotides per pitch. ▶supercoiling, ▶DNA

Twitchin: A myosin-activated protein kinase.

Two-Component Regulatory Systems: In bacteria, pairs of proteins transduce environmental signals. In one of the proteins, ca. 250 amino acids at the C-terminus and ca. 120 amino acids at the N-terminus are conserved. They control chemotaxis, virulence, nitrogen assimilation, dicarboxylic acid transport, sporulation, etc. They function by autophosphorylation of a histidine residue by the γ phosphate of ATP (see Fig. T133). The phosphate is then transferred to an aspartate, in the *response regulator*, that modifies regulatory activity of the C-terminal output domain. The system is also called a phosphorelay. A specific phosphatase may reset the system. Frequently, more than two components are involved. ▶[signal transduction](#); Itou H, Tanaka I 2001 J Biochem 129:343.

Figure T133. Two-component regulatory system

Two-Dimensional Gel Electrophoresis: In two-dimensional gel electrophoresis, the (protein) mixture is first separated by isoelectric focusing, and then separated by size using a slab of SDS polyacrylamide gel. Thus all proteins, except those rare molecules that have identical charge and molecular size, are distinguished. For the detection of small quantities of the molecules, they are either labeled radioactively or by non-radioactive means. A single two-dimensional gel slab permits the separation of hundreds or thousands of proteins at a time (see Fig. T134).

Figure T134. Two-dimensional gel electrophoresis of proteins. (Courtesy of ESA Inc. Chelmsford MA 01824-4771)

For the identification of proteins of very low abundance affinity purification may be required. The technique is used extensively in proteomic analyses. The definitive identification of proteins is hindered often by the fact that the concentration of individual

proteins may vary 5–7 orders of magnitude. The two-dimensional electrophoretic analyses of the proteome may have important potential for the understanding of disease development (Hanash S 2003 Nature [Lond] 422:226). In the immobilized pH gradient gel electrophoresis (IPG) the pH gradient is fixed in the acrylamide gel. In the differential in-gel electrophoresis (DIGE) uses two pools of proteins labeled with different fluorescent dyes and then separated in two dimensions. ▶[electrophoresis](#), ▶[isoelectric focusing](#), ▶[microchannel plate](#), ▶[FTICR](#), ▶[proteome](#), ▶[normalome](#); Hoving S et al 2002 Proteomics 2:127; Ros A et al 2002 Proteomics 2:151; Gromov PS et al 2002 Progr Biophys Mol Biol 80:3; <http://www.expasy.ch/ch2d/>; <http://proteomics.cancer.dk/>; <http://us.expasy.org/>; <http://www.wzw.tum.de/proteomik/lactis>.

Two-Hit Hypothesis: The two-hit hypothesis assumed that in order to develop cancer, two genetic alterations must take place in succession. Some chromosomal aberrations are also known as two-hit causes because two breaks are necessary to bring about an inversion or translocation. ▶[kinetics](#), ▶[Knudson two-mutation theory](#)

Two-Hybrid Method: Genetic constructs of yeast facilitate the study of protein-protein interactions. The GAL4 protein is both an enzyme and an inducer (see Fig. T135). The native GAL4 protein contains an N-terminal UAS (upstream activator sequence) DNA-binding region and a carboxyl-terminal transcription-activating region. These regions—in close vicinity—are required for the activation. Thus fusing the N-terminal of a protein (bait) and the C terminal of another protein (prey) can help study interaction between two proteins. If the two proteins interact, they reconstitute the link between the binding, and the activating domains and transcription (expression) of the reporter gene (represented by the turned on light bulb) may proceed. Thus to see expression, the DNA binding domain (DBD) must bind to the UAS element and contact established with the other protein element, which is often called *prey* and is attached to a transcriptional activator. The DBD + bait (hybrid I) and the prey + activator (hybrid II) are separately inactive. The expression of the downstream reporter gene requires interaction between the *two-hybrid* proteins. The most commonly used binding component is derived from the Gal4 or LexA proteins and the bacterial LacZ or luciferase is employed as a reporter. The receptor domain, usually called bait, may occur on a plasmid, which may also carry sequences to promote dimerization and thus the required protein interaction. The Gal bait (in contrast to the majority of LexAs) usually also contains nuclear localization sequences.

Efficient prey vectors may contain the VP16 activation domain or the Gal4 region II. The B42 bacterial activator is weaker than the other two but has affinity for a wider range of proteins and suppresses (squashes) the toxic effects that Gal4 and strong transcriptional activators may have on yeast. The two-hybrid method in yeast is very simple to use. Strains with the bait can be mixed and mated with strains with the prey and then plated on selective media where the interactions are readily detectable. The advantage of the two-hybrid method is that it can be used to test protein interactions, determine the amino acid sequences critical for interactions, and screen gene libraries for binding proteins or activators.

Figure T135. Two-hybrid method

The system is also suitable for testing any molecule (including aptamers) that may affect interactions, e.g., in the development of specific drugs. The system can be used in studies of the cell cycle and transcription factors, tumorigenesis, tumor suppression, etc. In some instances, positive (i.e., non-relevant for the purpose of the study) activation of the reporter gene may also occur. This interference can be reduced or eliminated by selective systems. False negative interactions are observed when the protein-protein interactions are low, there are problems with the intracellular folding of the proteins, or when other domains of larger proteins hinder proper interactions. The cases of false negatives may be low, yet may be very important in pharmacological studies. Some proteins may require a third (protein or non-protein) element for stabilization, bridging, or modification and then only a ternary complex is active. Systems have been constructed that prevent interactions between proteins. The URA3 reporter gene product converts fluoroorotic acid—with assistance of other genes—into fluorodeoxyuridine monophosphate, an analog of thymidylate synthase, which inhibits DNA

synthesis and can be used for contraselection. The two-hybrid method applied sequentially or simultaneously to large gene pools may detect interacting systems of genes. It may also place functionally unknown open reading frames into a biological context of a metabolic role. *Two-bait* systems have been developed for the possible detection of (allelic) variants of the same protein. Mammalian two hybrid procedures may facilitate the detection of interacting proteins in mammalian systems that depend on post-translational modifications not available in yeast cells. Protein-RNA interactions are studied by the *three-hybrid* systems. The *reverse two-hybrid* system detects mutations that are unable to bring the activation element to the DNA binding domain and thus cannot convert a potentially toxic compound to a toxic compound or into a suicide inhibitor. ▶galactose utilization, ▶split-hybrid system, ▶three-hybrid system, ▶reverse two-hybrid system, ▶four-hybrid system, ▶suicide inhibitor, ▶recruitment, ▶epistasis, ▶pleiotropy, ▶suppressor second site, ▶VP16, ▶one-hybrid binding assay, ▶aptamer, ▶microarray hybridization, ▶interaction trap, ▶genetic networks, ▶networks, ▶proteomics; Brent R et al 1997 Annu Rev Genet 31:663; Fields S, Song O 1989 Nature [Lond] 340:245; Shioda T et al 2000 Proc Natl Acad Sci USA 97:5220; Hirst M et al 2001 Proc Natl Acad Sci USA 98:8726; Fang Y et al 2002 Mol Genet Genomics 267:142; Uetz P 2002 Current Opin Chem Biol 6:57; Stelzl U et al 2005 Cell 122:957; <http://dip.doe-mbi.ucla.edu/>.

Two-Phase Mutation Model (TPM): In the TPM, microsatellite instability may be due to the gain or loss of a number of repeats. ▶IAM, ▶SMM, ▶microsatellite

Two-Photon Microscopy: In two-photon microscopy, a fluorochrome is excited almost simultaneously by two photons of lower energy. This allows reduced light scattering and less photo damage of the sample.

Two-Point Cross: The two-point cross involves differences at two gene loci, e.g., $AB \times ab$ or $Ab \times aB$.

Two-Step Synapsis: ▶topological filter

Two-Tailed Test: The two-tailed test estimates deviations in both directions from the mean.

Ty: Non-viral retroelements (retrotransposons) in the nucleus of budding yeast (*Saccharomyces cerevisiae*). Ty elements occur in several related forms and are designated Ty1 (25–30 copies), Ty2 (10 copies), Ty3 (2–4 copies), etc. The elements are flanked by long terminal direct repeats (251 – 371-bp) that are designated as δ for Ty1 and Ty2, and σ for Ty3. The open reading frame between the repeats (LTR) in Ty1 and Ty2 is identified as ϵ . Elements resembling these

terminal repeats, δ (ca. 100 copies), σ (20–30 copies), and τ (15–25 copies) are also found. The terminal repeats contain sequences identified as U3 (unique for 3'), R (repeated), and U5 (unique for 5' end) similarly to the designations in retroviruses. These LTRs contain the upstream gene activation sequence, TATA box, and polyadenylation, transcription, and termination signals. They also include the TG...CA bases involved in the integration of the reverse transcripts into the chromosomes. All the retroelements are generally flanked in the host by 5-bp target duplications. The open reading-frames, distinguished as TYA and TYB between the ends, are also similar and resemble retroposons of other organisms. The TYA protein may be processed through proteolysis into several smaller proteins involved in the formation of the shell of the VLP (virus-like particle). TYB contains genes for protease (*pro*), integrase (*int*), reverse transcriptase (*rt*) and RNase H (*rnH*) but no *env* gene is present as would be expected for retroviruses. Although most of the Ty elements and the independently standing termini are intact, some contain deletions up to a few kb, and the LTR sequences may be truncated. There may be apparent insertions and duplications within the Ty elements or inversion(s) involving parts of a LTR. The heterogeneity of the coding regions is due to base substitutions.

Ty retrotransposons transpose by synthesizing an RNA that is reverse-transcribed into DNA for integration. The Ty1 transcripts represent about 0.8% of the total RNA in the cell but the Ty cDNA is present in less than one copy per haploid cell before integration because of the inefficient processing of the transcript. The rate of Ty1 transposition is about 10^{-5} to 10^{-7} per element per cell division. The Fus3 protein kinase, the transcription factor TFIIB and nucleotide exchange repair modulate the transposition of Ty. The reverse-transcribed DNAs can integrate into Ty elements with the aid of recombination factors of the host and form tandem elements. RNA polymerase II transcribes them and the transcripts are polyadenylated. Transcription may be prevented by mutations symbolized as *spt* (suppressor of Ty). The transcription of Ty elements may be induced by sex pheromones synthesized by the *MATa* or *MATa* genes but not in the *MATa/Mat a* diploids. *MAT* homozygotes do not affect the transcription of Ty RNA. The Ty RNA can be packaged into virus-like particles (VLP). Proteolysis is involved in the processing of the TYA and TYB products, required for the completion of VLPs. The reverse transcription appears to be primed by tRNA^{Met}. Degradation of the template RNA is due to RNase H. During reverse transcription, recombination, sequence modifications, and deletions may occur at high frequency. Transcription of Ty is regulated by several *PST*

(suppressor of transposition), *ROC* (reducer of overproduction of transcripts), and *TYE* (Ty enhancer) genes. Presumably, about 100 host genes affect the Ty1 retrotransposition cycle. About half of them are involved in the production of the cDNA and the rest affect steps following Ty replication (Griffith JL 2003 et al 2003 Genetics 164:867). Transcription may be increased by exposure to UV light, ionizing radiation, chemical mutagens, and the culture media and it is elevated 20 fold at low temperature. The RAD52 group of recombinational repair genes inhibits the transposition of Ty. Insertion into and activation of these particular genes measure the frequency of transposition by genetically tagged Ty elements.

The VLP is made in the cytosol but must enter the nucleus for transposition to take place. Insertion of Ty into structural genes eliminates their function and reversion by excision is very rare because the target site is modified by the event. Insertion within non-coding sequences may activate or silence previously inserted elements. Ty1 and Ty2 elements appear to be distributed at random throughout the genome but the family of Ty3 elements is far more restricted. The Ty3 element inserts at the transcription initiation sites of tRNA genes by pol III. The transcription factors TFIIB and TFIIC are required for this type of insertions. The Ty1 element has preference for integration into the 5'-sequences of pol II-transcribed genes. Ty5 integrates preferentially into heterochromatin. Ty, δ , σ , and τ are commonly targeted to the vicinity of tRNA genes (hot spots). The insertions are usually directed into the leader sequences (promoter sites) or near the 5'-end of the coding region. Among the abundant Ty elements, recombination may occur and cause chromosomal rearrangements and deletions. Recombination is most common between LTR (δ) repeats. Gene conversion may also occur between these elements. Ty elements may incite deletions, inversions, and translocations with all the phenotypic consequences. The mutation rate within Ty elements was estimated to be 0.15 per Ty per replication cycle, i.e., about 1/15 of the retrotranspositions result in some types of mutation. Multiple copies of Ty1 may involve co-suppression, i.e., silencing of the elements (Garfinkel DJ et al 2003 Genetics 165:83). This rate of mutation is approximately 4 to 6 orders of magnitude higher than that in the rest of the nuclear genome but is comparable to that in RNA viruses. The high mutation rate is attributable to the lack of proofreading ability of the reverse transcriptase. The mutations in Ty (about 30% of all) occur within the seven bases of the primer-binding site (PBS) where minus strand replication is primed by a tRNA. Imprecise cutting by RNase H causes some mutations. Another error-prone event is the addition

of nucleotides immediately adjacent to the tRNA primer-binding site. After the replication system reaches the 5'-end, nucleotide additions take place at the 3'-end. After the second-strand transfer, partial DNA•DNA duplexes are formed and the recessed 3'-ends prime the completion of the double strand synthesis. As a consequence of the addition of nucleotides, the 3'-end of the minus strand cannot anneal precisely with the plus-strand DNA template. In order to reconstitute the 5'-LTR of the Ty, the mispaired 3'-primer ends are extended by reverse transcription. This process incorporates then the mispairs into the Ty element that will integrate into the yeast chromosome. The mismatches must then be fixed by DNA repair. Additional mutational mechanisms may also occur. These mutational processes are not unique features of the Ty elements but are also used by other retroelements. Retroviruses are somewhat different, however, because they show frameshift mutations and complex rearrangements. The Ty elements have been utilized as vectors (pGTy), as insertional mutagenic agents (transposon tagging), and for fusion of TyA proteins with certain proteins of interest, to facilitate the purification of epitopes. Similar transposable elements occur also in other fungi (*Candida*, *Pichia*, *Hansenula*). ▶retroposon, ▶retrotransposon, ▶transposition induction, ▶reverse transcription, ▶strong-stop DNA, ▶mating type determination in yeast, ▶protease, ▶integrase, ▶epitope, ▶*Saccharomyces cerevisiae*, ▶pol II, ▶pol I, ▶DNA repair, ▶fus3, ▶TFIIH, ▶VLP; Boeke JD et al 1988 Mol Cell Biol 8:1432; Jordan IK, McDonald JF 1999 Genetics 151:1341; Wickner RB 2001, p 473. Typing: The determination of the blood group antigens and HLA. It is a general classification by type. Also, DNA typing by fingerprinting using restriction enzyme-generated fragment pattern. ▶blood groups, ▶HLA, ▶DNA fingerprinting

Tyrosinase: ▶albinism

Tyrosine: A non-essential aromatic amino acid (MW 181.19), soluble in dilute alkali (see Fig. T136). Its biosynthetic pathway is with enzymes involved in parenthesis: Chorismate -> (chorismate mutase) -> Prephenate -> (prephenate dehydrogenase) -> 4-Hydroxyphenyl pyruvate -> (amino trans-ferase

with glutamate NH₃ donor) -> Tyrosine. Tyrosine can be derived also from phenylalanine by dehydroxylation. Tyrosine is a precursor for norepinephrine, epinephrine, 3,4-dihydroxy-phenylalanine (dopa), dopamine, and catechol that form the catecholamine family of animal hormones. ▶phenylalanine, ▶chorismate, ▶pigmentation of animals, ▶alkaptonuria, ▶tyrosinemia, ▶tyrosine aminotransferase, ▶tyrosine kinase, ▶animal hormones, ▶goiter, formula above.

Figure T136. Tyrosine

Tyrosine Aminotransferase (TAT, Richner-Hanhart syndrome): TAT converts tyrosine into p-hydroxyphenylpyruvate. Glucocorticoid hormones induce it. TAT deficiency occurs rarely in humans and is controlled by a recessive gene (ca. 11 kb, 12 exons) in human chromosome 16q22.1-q22.3 (and mouse in chromosome 8). The condition involves elevated level of tyrosine and in some cases an increased urinary excretion of p-hydroxyphenylpyruvate and hydroxyphenylacetate. The disease generally involves corneal ulcer, palm keratosis (callous skin), and mental and physical retardation. The mitochondrial enzyme is under the control of another gene. A TAT regulator gene may be located in the human X-chromosome and glutamic oxaloacetic transaminase (16q21) also regulates its activity. ▶tyrosine, ▶tyrosinemia

Tyrosine Hydroxylase (TYH): TYH is encoded in human chromosome 11p15 (mouse chromosome 7), which controls the synthesis of dopamine from phenylalanine. Dopamine is a hormone involved with adrenergic neurons, the sympathetic nerve fibers that liberate norepinephrine when an impulse passes the nerve synapse. This enzyme may play a key role in fetal development and in manic depression. The microsatellite sequence in the first intron serves normally as a transcriptional enhancer of the gene. ▶tyrosine, ▶manic depression, ▶DOPA; Albanèse V et al 2001 Hum Mol Genet 10:1785.

Tyrosine Kinases (protein tyrosine kinase): Tyrosine kinase activity is essential for many processes of the signal transduction, tissue differentiation involving oncogenesis, and signaling to immunoreceptors. The most frequently activated proteins are phospholipase C-γ, phosphatidylinositol 3-kinase, and GTPase activating kinase. ▶oncogenes ABL, ▶ARG, ▶Btk, ▶Btk, ▶FES, ▶FGR, ▶FLT, ▶FHS, ▶ERBB1, ▶Fyn, ▶RAF, ▶SRC, ▶KIT, ▶LCA, ▶Lyn,

Tyrosine Phosphatases (protein tyrosine phosphatase, PTP): The PTP family of enzymes has at least 40 known members. Some have properties of transmembrane receptor proteins (RPTP) and the cytosolic forms have a characteristic ca. 240-amino acid catalytic domain. Each PTP has also a phosphate-binding, 11-residue motif containing catalytically active Cys and Arg. The proteins have critical roles in signal transduction relevant to growth, immune response, proliferation, and differentiation. Dimerization negatively regulates the activity of receptor tyrosine phosphatase- α . ►signal transduction, ►PTK, ►synaps; Stetak A et al 2001 Biochem Biophys Res Commun 288:564; substrates: Tiganis T, Bennett AM 2007 Biochem J 402:1; Liu Y et al 2007 Nature Rev Immunol 7:202.

Tyrosine Protein Kinase: ►tyrosine kinase, ►phosphorylase

Tyrosine Transaminase: ►tyrosine aminotransferase

Tyrosinemia (FAH): The recessive gene responsible for the anomaly is in human chromosome 15q23-q25. Its prevalence is about 1/2,000 live births. FAH involves increased levels of tyrosine in the blood and a lack of

p-hydroxyphenylpyruvate oxidase, but the primary enzyme defect appears to be fumarylacetoacetase deficiency leading to accumulation of succinylacetone and succinylacetoacetate. Defects in porphyrinogenesis appear secondary. Because of the deterioration of the liver, as secondary symptoms, accumulation of methionine and other amino acids in the blood and urine is frequent. The particular odor of the body fluids may be due to α -keto- γ -methiolbutyric acid. Prenatal diagnosis of FAH relies on amniotic fluid analysis for succinylacetolactone or measurement of fumarylacetoacetase in cultured amniotic cells. Low tyrosine diet alleviates the symptoms but to avoid liver cancer, liver replacement before age two is advisable. This type of tyrosinemia involves various kinds of chromosomal anomalies. Tyrosinemia II (16q22.1-q22.3) is a deficiency of tyrosine aminotransferase. Tyrosinemia Type III (12q24-qter) is due to a deficiency of 4-hydroxyphenyl-pyruvate dioxygenase. This disease does not usually involve dysfunction of the liver. The condition can be detected prenatally but carriers cannot be identified. Mice mutants homozygous for FAH but heterozygous for alkaptonuria were partially normalized in their hepatocytes. The tyrosine degradation pathway: tyrosine \rightarrow (tyrosinemia type II) \rightarrow 4-OH-phenylpyruvate \rightarrow (tyrosinemia type III) \rightarrow homogentisic acid \rightarrow (alkaptonuria) \rightarrow maleylacetoacetate \rightarrow fumarylacetoacetate \rightarrow (tyrosinemia type I) \Rightarrow fumarate and acetoacetate. ►tyrosine aminotransferase, ►genetic screening, ►methionine adenosyltransferase deficiency, ►methionine biosynthesis, ►amino acid metabolism, ►liver cancer, ►mosaic, ►gene therapy, ►alkaptonuria; Jorquera R, Tanguay RM 2001 Hum Mol Genet 10:1741.

Tyrosinosis: ►tyrosine aminotransferase

Historical vignettes

Aristotle reviews the ancient theories of sex determination, but finds them unsatisfactory:

“Some suppose that the difference [between sexes] exists in the germs from the beginning; for example, Anaxagoras and other naturalists say that the sperm comes from the male and that the female provides the place [for the embryo], and that the male comes from the right, the female from the left, since in the uterus the males are at the right and the females at the left. According to others, like Empedocles, the differentiation takes place in the mother, because, according to them, the germs penetrating a warm uterus become male, and a cold uterus female...” (Generation of Animals, Book IV, Part I, Para. 2).

Peter Starlinger (discoverer of insertion mutations in bacteria with Heinz Saedler in 1972 [Biochimie 54:177]) noted in 2005 in Annu Rev Plant Biol 56:1

“It was only then that we realized the relation of these element to McClintock's transposable elements, in spite of the fact that I had known McClintock's work since my student days, and in spite of a series of seminars that we had held on this topic in the institute in Cologne. Sometimes we are blind!”

U

U: Denotes uracil. ►pyrimidines

U: Symbol for uranium.

U-937: Refers to human monocyte line. ►monocytes

U Protein (unwinding protein): Unwinds the DNA strands at a distance from a ►nick. (See Basak S, Nagaraja V 2001 J Biol Chem 276:46941).

U RNA (ubiquitous RNA): Denotes a snRNA. Its transcript has a 2,2,7-trimethyl guanosine cap and may have modified U residues; it does not have a poly-A tail. ►snRNA, ►snurposome, ►cap, ►poly-A tail

U1 RNA: This has complementary sequences to the 5' consensus sequences of the splice sites and probably plays a role in mRNA processing from the primary transcript. Mutated U1 snRNA may be a strong inhibitor of gene expression (Fortes P et al 2003 Proc Natl Acad Sci USA 100:8264). ►hnRNA, ►RNA; McNamara-Schroeder KJ et al 2001 J Biol Chem 276:31786.

U2 RNA (snRNA): Apparently, this recognizes the 3' end of introns at the lariat and is involved in splicing. ►lariat, ►splicing, ►introns

U3 snRNP: Most abundant of the U RNA ($\approx 10^6$ molecules/cell) processes near the 5' end of the ribosomal RNA transcripts. It stays on and generates a 5' knob characteristic of rRNA only. Binding U3 of the snRNP initiates processing, especially the transcripts of 18S rRNA. ►rRNA, ►snRNP, ►ribosome; Venema J et al 2000 RNA 6:1660.

U7 snRNA: Involved in the processing of the 3' end of the histone pre-mRNAs. In *Drosophila*, it contains 71 nucleotides. In vertebrates it is located in the Cajal bodies. ►Cajal body; Dominski Z et al 2003 Proc Natl Acad Sci USA 100:9422.

U8 snRNP: Required for the upstream cleavage of 5.8S and for cutting off 28S RNA ca. 500 nucleotides at the 3' end. ►rRNA, ►snRNP, ►ribosome; Peculis BA, Steitz JA 1994 Genes Dev 8:2241.

U12 snRNP: A spliceosomal component along with other U snRNAs. ►spliceosome; Otake LR et al 2002 Mol Cell 9:439.

U14 snRNP: A maturase for 18S rRNA. ►ribosome; Newman DR et al 2000 RNA 6:861.

U22 snRNP: Essential for processing both ends of 18S rRNA, separated by about 2,000 nucleotides.

UAA: Refers to the ochre codon of translation termination. ►code genetic, ►translation termination

U2AF: A protein assisting U2 snRNA recognition. U2AF family proteins regulate both steroid hormone receptor-mediated transcription and alternative splicing (Dowhan DH et al 2005 Mol Cell 17:429). Phosphorylated DEK protein assists U2AF in intron removal (Mendel Soares LM et al 2006 Science 312:1961). ►U2 RNA, ►alternative splicing; Guth S et al 2001 Mol Cell Biol 21:7673.

UAG: Refers to the amber codon of translation termination. ►code genetic, ►amber suppressor

UAS: Denotes upstream activating sequences (which regulate gene transcription). They behave in the same manner as enhancers. UAS encode DNA-binding proteins, e.g., the GAL4 UAS codes for a 100 kDa protein and protects its 17 bp palindromic sequence against DNase I digestion or methylation. These proteins bind to special DNA sequences and to other proteins in the transcriptional complex. Transcriptional activation and binding may rely on more than one tract of amino acids. ►promoter, ►galactose utilization, ►two-hybrid method; Blackwood EM, Kadanaga JT 1998 Science 281:61.

uAUG: In 3 to 10% of the RNA transcripts translation initiation codons occur in the 5'-untranslated sequences (5'-UTR) of viruses, fungi, plants and mammals. The open reading frame due to uAUG may have an untranslated intercistronic region relative to the downstream ORF or they may overlap or it may be in-frame. uAUGs may have regulatory functions. (See Rose JK, Iverson L 1979 J Virol 32:404).

UBC2 (E2): Refers to ubiquitin-conjugating enzymes. From UBC ubiquitin is transferred to a lysine residue of the target protein. Ubc2/Rad6 - Rad18 proteins have functions in both proteolysis and DNA repair. Ubc2 proteins occur in many isoforms within the same organism. ►ubiquitin, ►E2, ►Rad 18, ►isoform; Ptak C et al 2001 Mol Cell Biol 21:6537.

UBC3/Cdc34: A ubiquitination enzyme required for G1→S phase transition in the cell cycle. ►ubiquitin, ►Cdc34

Ubc9: A ubiquitin interacting protein. It is involved in the control of the cell cycle from G2→M, and in the degradation of diverse proteins in a variety of organisms. ►ubiquitin, ►UBL; Kaul S et al 2002 J Biol Chem 277:12541.

UbcD1: This ubiquitin protein of *Drosophila* degrades some telomere associated proteins and thus controls the proper detachment and attachment of the telomeres during mitosis and meiosis. ►telomere,

►ubiquitin; Bocca SN et al 2001 *Biochem Biophys Res Commun* 286:357.

UBE3A: A ubiquitin ligase gene plays a role in Angelman syndrome. ►ubiquitin, ►Angelman syndrome; Kishino T et al 1997 *Nature Genet* 15:70.

Überoperon: Includes gene neighborhoods where individual operons may show rearrangement in different species, yet remain in the functional and regulatory context (Lathe WC III et al 2000 *Trends Biochem Sci* 25:474). Rogozin and associates (Rogozin IB et al 2002 *Nucleic Acids Res* 30:2212) named this phenomenon genome hitchhiking. The largest such neighborhood in prokaryotes includes 79 genes. Most, albeit not all these genes, share a known functional role. ►operon, ►supraoperon

UBF (upstream binding factor): In association with protein SL-1 UBF, controls the transcription of rRNA genes by RNA polymerase I. These protein factors differ even among closely related species; they are members of the high mobility group proteins. ►high mobility group proteins, ►transcription factors, ►SL1; Santoro R, Grummt I 2001 *Mol Cell* 8:719; Chen D, Huang S 2001 *J Cell Biol* 153:169; Stefanovsky VY et al 2001 *Mol Cell* 8:1063.

Ubiquilin: A protein that stimulates the biosynthesis of neurofibrillary tangles in Alzheimer's disease and Lewy bodies in Parkinson's disease. ►Alzheimer's disease, ►Parkinson's disease, ►Lewy body, ►tau; Mah AL et al 2000 *J Cell Biol* 151:847.

Ubiquinones (coenzyme Q): Lipid-soluble benzoquinones mediate electron transport. The reduced form is a potent lipid-soluble antioxidant capable of inhibiting lipid peroxidation. ►cytochromes, ►lipids, ►peroxides; Elias M et al 2001 *J Biol Chem* 276:48356.

Ubiquitin: This acidic polypeptide (~76 amino acids) is ubiquitously present in prokaryotic and eukaryotic cells. It may be associated with H2A histone and the conjugate is called UH2A. It binds to other proteins and proteolytic enzymes and then degrades the ubiquitinated proteins. In the majority of cases the degradation takes place in the cavity of the (20S–26S) proteasomes, cylindrical complexes of proteases, or the ligand-bound molecule can be internalized into vacuoles and degraded by lysosomal enzymes. Ubiquitination is involved in many aspects of cellular regulation, DNA repair, stress response, cell cycle progression, formation of the synaptonemal complex, signal transduction and apoptosis. Ubiquitin stress alters proteasome composition by enhanced loading of deubiquitinating Ubp6 to the proteasome (Hanna J et al 2007 *Cell* 129:747). A cascade of conjugating, activating and carrier enzymes recognizes ubiquitin. The E1 enzyme forms a thiol ester with ubiquitin using ATP energy.

The E1-ubiquitin complex then transfers UB to the carrier E2 which with the aid of E3 ligases mediates the association of E2 with the target proteins. For catalysis, the E3 ligases use either a HECT or a RING finger domain. The ubiquitin E3 ligase complexes may be SCF (Skp1-Cdc53/CUL1-F-box proteins), APC (anaphase promoting complex) and the VCB-like family (VHL-ElonginC/ElonginB) proteins. SCF-βTrCP is also a ubiquitin ligase. Several other molecules are also involved. The ubiquitin complex is degraded by deubiquitinating cysteine protease enzymes (DUBP). The signals for degradation are PEST sequence at the C-ends, N-end rule domains and phosphorylation. The human ubiquitin genes are encoded at chromosome 17p11.1-p12 and polyubiquitin at 12q24.3. Polyubiquitin is a chain of several ubiquitin molecules linked by lysine (K-48 or K-63). Some protein molecules may be degraded co-translationally in case they are defective or if their folding is slow. Ubiquitin may have non-destructive functions as well such as processing signaling molecules in the cell and facilitating the expression of genes (Finley D 2001 *Nature [Lond]* 412:283; Mukhopadhyay D, Riezman H 2007 *Science* 315:201). ►monoubiquitin, ►histones, ►proteolytic, ►lactacystin, ►lysosomes, ►proteasomes, ►PEST, ►Ubc, ►UBP, ►CDC34, ►Ubl, ►PIC, ►sentrin, other entries listed separately, ►SCF, ►Skp1, ►Cul-lins, ►D box, ►K-box, ►F-box, ►APC, ►VHL, ►E1, ►E2, ►E3, ►Socs-box, ►Rbx1, ►PEST, ►N-end rule, ►destruction box, ►multivesicular body, ►IκB, ►antigen processing and presentation, ►lid, ►SUMO, ►Huntington's chorea; Hershko A, Ciechanover A 1998 *Annu Rev Biochem* 67:425; Pickart CM 2001 *Annu Rev Biochem* 70:503; Weismann AM 2001 *Nature Rev Mol Cell Biol* 2:169; Conaway RC et al 2002 *Science* 296:1254; Walden H et al 2003 *Nature [Lond]* 422:330; Liu YC 2004 *Annu Rev Immunol* 22:81; regulation: Gao M, Karin M 2005 *Mol Cell* 19:581; unfolding: Irbäck A et al 2005 *Proc Natl Acad Sci USA* 102:13427; ubiquitin chain assembly: Hochstrasser M 2006 *Cell* 124:27; ubiquitin binding domains: Harper JW, Schulman BA 2006 *Cell* 124:1133.

Ubiquitous RNA: ►URNA

Ubistatins: These are block binding ubiquitinated substrates to the proteasome. ►ubiquitin; Verma R et al 2004 *Science* 306:117.

UBL: Refers to ubiquitin (Ubc9) interacting protein operating on many different proteins under various names such as sentrin and SUMO-1. ►ubiquitin, ►Ubc, ►E2, ►SUMO

UBP: A group of (16 in budding yeast) ubiquitin degrading enzymes or de-ubiquitinating enzymes or isopeptidases. UBPs may regulate gene silencing,

differentiation and cell division (cyclins, Cdks, MPF, etc.). ▶ubiquitin, ▶cell cycle, ▶cyclins, ▶CDK, ▶silencer, ▶MPF, ▶morphogenesis; Lin H et al 2000 Mol Cell Biol 20:6568.

UBR: An enzyme that mediates the formation of thioester with ubiquitin and UBC. ▶UBC; Kwon YT et al 1998 Proc Natl Acad Sci USA 95:7898.

UCE (upstream control elements): These regulate transcription. ▶regulation of gene activity

UDG (uracil-DNA-glycosylase): This repair enzyme is capable of removing accidentally incorporated U or deaminated C, which is followed by the removal of the apyrimidinic site with the aid of AP endonuclease. There are two nuclear-coded UDG enzymes in the mammalian cells; one of them is in the mitochondria. ▶DNA repair, ▶excision repair, ▶AP endonuclease; Dinner AR et al 2001 Nature [Lond] 413:752.

UDP: Uridine diphosphate is formed from uridine monophosphate and gives rise to uridine triphosphate by using ATP as the phosphate donor (see Fig. U1).

Figure U1. UDP-5'diphosphate Na

UEP: ▶unit evolutionary period

UEP (unique event polymorphism): Includes SNIPS, INDELs and microsatellite sites that facilitate characterization of haplotypes.

UGA: Refers to opal stop codon. ▶code genetic

UGT/UGPGT (uridinediphosphate-glucuronosyltransferase): Detoxifies various lipid-soluble toxins by conjugation with glucuronic acid, makes them water-soluble, excretable and may prevent mutation and cancer. Its phosphorylation controls substrate-specificity (Basu NK et al 2005 Proc Natl Acad Sci USA 102:6285). ▶Crigler-Najjar syndrome

UH2A: ▶ubiquitin

UhpB: *E. coli* kinase involved in the regulation of sugar phosphate transport.

uidA: The gene for β-glucuronidase. ▶β-glucuronidase

Ulcer: A condition characterized by corruption of the surface or deeper cell layers of the body, e.g., gastric ulcer, an ulceration inside the stomach or diabetic ulcers of the legs, or genital ulcers in the case of sexually transmitted disease. ▶Crohn's disease

Ulcerative Colitis: This is an inflammatory bowel disease (IBD) like Crohn's disease. It is apparently under the control of several chromosomes and genes. ▶inflammatory bowel disease

Ullrich Congenital Muscular Dystrophy (Ullrich disease): ▶muscular dystrophy

Ullrich-Turner Syndrome: This is the the same as Turner's syndrome.

Ulna: The larger bone of the forearm opposite the thumb.

Ulnar-Mammary Syndrome: ▶Schinzel syndrome

Ultimate Mutagen: Some chemical substances (promutagens) become mutagenic only after activation. In this process, first proximal mutagens are formed that may be subsequently converted to a form (ultimate mutagen) that is genetically most reactive with the DNA. ▶activation of mutagens

Ultrabar: ▶Bar mutation

Ultracentrifuge: Laboratory equipment suitable for the separation of cellular organelles and macromolecules by high (over 20,000 revolution/minute) centrifugal force in an evacuated and refrigerated chamber. At maximal speed it may exceed the gravitational force several hundred thousand times. The *analytical ultracentrifuge* monitors continuously or intermittently the boundary of movement of macromolecules in a solute (e.g., Cs₂SO₄). The more commonly used *preparative ultracentrifuge* fractionates organelles or macromolecules in sucrose or CsCl. The suspended material forms a band corresponding to its density and the density of the solute. Chloroplasts in sucrose gradients can be identified by color; DNA bands in CsCl can be identified by staining with the dye ethidium bromide. The bands, containing homogeneous material, can be removed by careful suction from the centrifuge tubes or by drop-wise collection through a hole punctured at the bottom with a syringe needle. (See Laue TM, Stafford WF III 1999 Annu Rev Biophys Biomol Struct 28:75; ▶Lamm equation).

Ultraconserved DNA Elements (UCE): 200-base pair or shorter or longer and entirely or almost entirely identical sequences in the human, rat and mouse genomes and are well conserved in chicken, dog and fish as well. They occur frequently in overlapping exons in genes involved in RNA processing or in introns or nearby genes regulating transcription and

development. Sequences longer than 100 nucleotide are common in both RNA and DNA binding and in transcriptional regulation. Less than 50 nucleotide ultraconserved elements are common in microRNA, other non-coding RNA and transcription factor binding sites. The ultraconserved sequence elements in whole human and mouse genomes follow the power law distribution and apparently have evolutionary significance (Salerno W et al 2006 Proc Natl Acad Sci USA 103:13121). Their distribution along the chromosomes is not random but they are absent in human chromosome 21 and their numbers are significantly depleted in the case of segmental duplications and copy number variants. Their conservation across phylogenetic entities indicates positive selection rather than neutrality in evolution. UCEs indicate enhancer-like activity of these elements (Derti A et al 2006 Nature Genet 38:1216). ▶[mutation neutral](#), ▶[networks](#); Bejarano G et al 2004 Science 304:1321.

Ultradian: Occurring periodically but less frequently than once a day. ▶[circadian](#)

Ultrasonic (ultrasound): Refers to radiation in excess of 2×10^4 hertz/second, generally 5×10^5 hertz/sec. It is used for breaking down cells, treatment of arthritis and for tomographic examination or sonography, etc. Prenatal ultrasonic scanning of fetuses is widespread in the developed world and there is no convincing evidence of adverse effects. There has been much speculation about increase of left-handedness, lower cognitive development and cancer but experimental data have not confirmed these conjectures in large human populations. Ultrasound increases the delivery efficiency of exogenous nucleic acid to the intended target. The ideal system enhances gene expression in the target without having any effect on non-target tissues. Ultrasound may be able to provide this localization in somatic gene therapy as well. Low doses of about 100 mW cm^{-2} do not appear to have lasting and harmful effects. ▶[arthritis](#), ▶[tomography](#), ▶[sonography](#); see reviews in Prog Biophys Mol Biol 93:2007.

Ultrastructure: A fine structure beyond the resolution of the light microscope.

U

Ultrathin-Layer Gel Electrophoresis: Along with capillary microelectrophoresis it is well suited for rapid automated separation of biopolymers, e.g., nucleic acids as needed for the genome sequencing projects. (See Guttman A, Ronai Z 2000 Electrophoresis 18:3952).

Ultraviolet Light (UV): Refers to emission below the wavelength of violet (400–424 nm). UV-A has the most effective emission between 315 and 400 nm, UV-B between 280 and 315 nm and UV-C between 200 and 290 nm wavelengths. Nucleic acids have maximal absorption at about 260 nm. The absorption

maximum may depend on base composition and pH. The maximal genetic effects of UV light coincide with the absorption maximum of nucleic acids. The major genetic effect of UV-B light is the generation of pyrimidine dimers and pyrimidinones. UV-A causes the production mainly of oxoguanine and reactive peroxides (Besaratina A et al 2005 Proc Natl Acad Sci USA 102:10058) and this part of the UV spectrum is particularly carcinogenic if the DNA repair system is inefficient (Kozmin S et al 2005 Proc Natl Acad Sci USA 102:13538). Another study has indicated that UV-A-induced cyclobutane pyrimidine dimers are the major cause of DNA lesions in the human skin (Mouret S et al 2006 Proc Natl Acad Sci USA 103:13765). These compounds may damage the DNA and interfere with replication and transcription and can cause mutation and induce cancer. UV-B has immunosuppressive potential whereas UV-A is inert in this respect but it may suppress the UV-B effects. This protective effect is due to the induction of skin heme oxygenase. Oxidation of the membrane proteins may affect the signal transduction pathways and activate genes of the cellular defense systems. In prokaryotes, the LexA repressor is inactivated leading to the upregulation of genes mediating mutation, recombination and DNA repair. In yeast, cell cycle genes and various kinases are activated. In animal cells, AP and NF- κ B transcription factors may be activated through the RAS signal transduction pathways. In plant cells, UV exposure may increase the synthesis of UV-absorbing flavonoids and phenylpropanoids and activates the octadecanoid defense pathway of fatty acids and generates less than 0.2 cyclobutane dimers per gene. In plants, transposons like *Mu* may enhance the mutagenic effects of UV-B radiation. Ultraviolet light in general has low penetration into biological material and a few cell layers may completely trap it. Nearly 100 genes of *Arabidopsis* are activated by UV-B and 7 are repressed (Ulm R et al 2004 Proc Natl Acad Sci USA 101:1397). The DNA must have a protection mechanism to convert dangerous electronic excitations by UV into less harmful vibrational energy and assure photostability (Satzger H et al 2006 Proc Natl Acad Sci USA 103:10196). ▶[DNA repair](#), ▶[genetic repair](#), ▶[physical mutagens](#), ▶[light response elements](#), ▶[light-sensitivity diseases](#), ▶[signal transduction](#), ▶[RAS](#), ▶[cyclobutane](#), ▶[pyrimidine dimer](#), ▶[8-oxodeoxyguanine](#), ▶[flavonoids](#), ▶[phenylpropanoids](#), ▶[fatty acids](#), ▶[electromagnetic radiation](#), ▶[Mu](#), ▶[JUN](#), ▶[excimer](#), ▶[melanocortin](#)

Ultraviolet Photoproducts: ▶[cyclobutane ring](#), ▶[pyrimidine-pyrimidinone](#), ▶[Dewar product](#), ▶[cis-syn photoproduct](#), ▶[translesion pathway](#), ▶[DNA repair](#)

Ultraviolet-Sensitivity Syndrome (UV^S S): RNA synthesis is inhibited in the cells by ultraviolet light. It appears to be different from xeroderma pigmentosum but is similar to the Cockayne syndrome. Ultraviolet-sensitivity is caused by a defect in the RAD genes required for genetic repair. ▶[xeroderma pigmentosum](#), ▶[Cockayne syndrome](#)

Ultraviolet Spectroscopy: Used to measure the absorption of (\approx monochromatic) UV light and thus qualitatively or quantitatively identifies molecules such as DNA and RNA.

Umbilical Cord: Cord, which attaches the fetus to the mother during pregnancy. The placental blood in the umbilical cord contains stem cells suitable for repopulating the bone marrow. ▶[stem cells](#)

UME: Denotes a unique mutational event which is a marker of evolutionary significance.

UML: Provides guidelines for data macromolecular structure and function presentation (Booch G et al 1997 The Unified Modelling Language User Guide, Addison-Wesley, Boston, Massachusetts).

UMP: This denotes uridine monophosphate. ▶[UDP](#)

UMU (UV mutagenesis): Genes *UmuC* and *UmuD* are involved in repairing the DNA damaged by ultraviolet light. UmuD' is a post-translationally processed active form of the UmuD protein. ▶[DNA repair \[SOS repair\]](#), ▶[translesion pathway](#)

Unami: Describes the taste of monosodium glutamate, a flavor enhancer in some oriental foods. ▶[taste](#)

Unbalanced Chromosomal Constitution: Parents heterozygous for inversions or translocations are functionally normal but may transmit to their offspring (unbalanced) duplication-deficiency gametes resulting in various physical and mental disabilities depending on the chromosomal region(s) involved (see Fig. U2). The frequency of unbalanced gametes (duplication/deficiency and duplication and deficiency) is more than 2% in the conceptuses.

This is, however, the lowest estimate because very frequently pregnancy is terminated before the current methods of analysis can detect fertilization. Even greater is the uncertainty about the frequency of chromosomal anomalies in the human sperm and egg that are extremely difficult to analyze cytologically. An unbalanced karyotype may be due to trisomy (in ~ 20 –30% of spontaneous abortions). Monosomy has been observed in about 5 to 10%, triploidy in 6 to 7%, and tetraploidy in 2 to 4% of the spontaneously aborted fetuses. Although spontaneous abortion is extremely undesirable, suffering due to chromosomal anomalies experienced by live offspring is far more. There is no effective cure for unbalanced chromosomes. ▶[translocation](#), ▶[inversion](#); Levy B et al 1998 Genet Med 1:4.

UNC-6: A protein of the netrin family in *Caenorhabditis elegans* which guides ventral migration of the axon growth cone. The 407-amino acid TGF- β -like protein

Figure U2. Unbalanced Chromosomal constitution inherited from phenotypically normal carrier parents. Left: Deficiency for the short arm of Chromosome 18. Middle: Duplication of the tip of the short arm of Chromosome 3. (Courtesy of Dr. Judith Miles). Right: Duplication of part of the long arm of Chromosome 4, resulting from a translocation heterozygosity involving Chromosomes 20 and 4. (Courtesy of Dr. D.L. Rimoin)

encoded by the UNC-129 gene has a similar function. ▶[netrins](#), ▶[semaphorins](#), ▶[TGF](#); Merz DC et al 2001 Genetics 158:1071.

UNC-33: A *Caenorhabditis* protein regulating axon extension. ▶[CRMP](#), ▶[axon](#); Ricard D et al 2001 J Neurosci 21:7203.

UNC-43: Encodes a calcium/calmodulin-dependent serine/threonine kinase type II and its mutation is responsible for multiple behavioral defects in *Caenorhabditis*. (See Sagasti A et al 2001 Cell 105:221).

unc-86 (uncoordinated): The *Caenorhabditis* gene has a pivotal role in determining neural identities. (See Burglin TR, Ruvkun G 2001 Development 128:779).

Uncertainty: ▶[Heisenberg's uncertainty](#)

Uncharged tRNA: This has no amino acid attached to it. ▶[tRNA](#)

Uncoating: During the initiation of infection the viral genome dissociates from the other constituents of the virus particle and is injected into the bacterium (see Fig. U3).

Figure U3. Uncoating of phage DNA

U

Uncompetitive Inhibitor: ▶[regulation of enzyme activity](#)

Uncoupling Agent: This uncouples electron transfer from phosphorylation of ADP, e.g., dinitrophenol. ▶[cold-shock proteins](#)

Uncoupling Protein (mitochondrial UCP): Uncouples oxidative phosphorylation from ATP synthesis and generates heat to safeguard against cold. Noradrenaline and adrenalin regulate it. UCP-3 is a member of

the mitochondrial transporter family in the skeletal muscles and controls metabolic rate and glucose homeostasis. UCP-1 is present in the brown adipose tissue and is involved in fat combustion and heat generation. UCPs play an apparent role in obesity, macrophage-mediated immunity and in the control of ROS. ▶[ROS](#); Jarmuszkiewicz W 2001 Acta Biochim Pol 48:145.

Underdominance: Refers to inferiority in performance or fertility or proportion of hybrids in feral populations. It may be caused by Robertsonian fusion, transposable element, meiotic drive, post-implantation selection, etc. ▶[overdominance](#), ▶[Robertsonian translocation](#), ▶[meiotic drive](#); Davis S et al 2001 J Theor Biol 212:83.

Underwinding: Characterizes negative supercoiling. ▶[supercoiling](#)

Unequal Crossing Over: Occurs between repeated sequences in the gene that may pair obliquely and therefore in the recombinant strands may have either more or less copies of the sequences than in the parental ones (see Fig. U4).

Figure U4. Unequal crossing over

The extra DNA material may not be needed for the species and thus can be used for evolutionary experimentation and may contribute to the evolution of new function(s). The frequency of such events may vary, e.g., in *Arabidopsis* $\sim 3 \times 10^{-6}$ has been observed. This estimate is within the range of mutation frequency and lower than that found at the *Bar* locus of *Drosophila* where unequal crossing over was first identified at a variable rate of 0.03 to 0.11. ▶[duplication](#), ▶[Bar locus](#), ▶[intragenic recombination](#); Bridges CB 1936 Science 83:210.

UniBLAST: Provides information on UniGene clusters, which are similar to the one interested in. ▶[UniGene](#), ▶[BLAST](#)

Unidentified Reading Frame: ▶[URF](#)

Unidirectional Replication: The replication fork moves only in one direction, left or right from the origin. ▶[replication fork](#), ▶[bidirectional replication](#); Maisnier-Patin S et al 2001 J Bacteriol 183:6065.

Unified Genetic Map: Such a map represents similarities in the distribution of nucleotide sequences across phylogenetic groups and is expected to not only

provide tools for evolutionary studies, but also assist in transferring economically advantageous genes to crops. The ancestral chromosomal pattern is shared between many species. Unique sequences characterize species that are more closely related. ►SCEUS, ►evolution, ►comparative maps, ►CATS, ►mapping genetic, ►physical map, ►integrated map; O'Brien SJ et al 1993 *Nature Genet* 3:103.

Unfolded Protein Response (UPR): The accumulation of unfolded proteins in the endoplasmic reticulum (ER) activates the transcription of molecular chaperones such as BiP, GRP, calreticulin and protein disulfide isomerase in the nucleus so that protein folding can proceed as needed. Misfolded proteins may, however, lead to cell death if UPR cannot alleviate the problems and reactive oxygen species accumulate (Haynes CM et al 2004 *Mol Cell* 15:767). UPR signaling is mediated by endoplasmic reticulum transmembrane protein, Ire1 (inositol-requiring kinase 1), which has both kinase and nuclease domains, and by PERK (protein kinase-like endoplasmic reticulum kinase). Protein P58^{IPK} is a cytoplasmic co-chaperone and is associated with the endoplasmic reticulum protein translocation channel Sec61 complex. P58^{IPK} recruits heatshock protein 70 (HSP70) chaperone to the cytosolic face of Sec61. Proteins that enter slow ER can be exposed to proteasome in a co-chaperone dependent manner and thus the unfolded protein overload is reduced (Oyadomari S et al 2006 *Cell* 126:727). BAX and Bak proapoptotic proteins activate IRE1 α signaling and provide a physical link between the core apoptotic pathway and UPR (Hetz C et al 2006 *Science* 312:572). Various adverse physiological conditions, toxins, inhibitors of the calcium pump, genetic defects altering protein structure, etc. evoke UPR. Proteasome inhibitors disrupt UPR in myeloma cells (Lee A-H et al 2003 *Proc Natl Acad Sci USA* 100:9946). Sialoglycolipid ganglioside can induce UPR and neuronal apoptosis (Tessitore A et al 2004 *Mol Cell* 15:753). Mutations in the editing domain of alanyl-tRNA synthetase disrupt fidelity of translation leading to misfolded proteins, cell death and neurodegeneration (Lee JW et al 2006 *Nature [Lond]* 443:50). ►endoplasmic reticulum, ►BiP, ►GRP, ►calreticulin, ►PDI, ►UPR, ►proteasome, ►gangliosides, ►apoptosis, ►BAK, ►BAX, ►endoplasmic reticulum-associated degradation, ►Sec61, ►heat-shock proteins; Rügsegger U et al 2001 *Cell* 107:103; Ma Y, Hendershot LM 2001 *Cell* 7:827; Calfon M et al 2002 *Nature [Lond]* 415:92; Kaufman RJ et al 2002 *Nature Rev Mol Cell Biol* 3:401; Harding HP et al 2002 *Annu Rev Cell Dev Biol* 18:575; Ma Y, Hendershot LM 2004 *Nature Rev Cancer* 4:966; Schröder M, Kaufman RJ 2005 *Annu Rev Biochem* 74:739; protein quality control: Bakau B et al 2006 *Cell* 125:443.

UNG (uracil nucleotide DNA glycosylase): This DNA repair enzyme removes mis-incorporated uracil from the DNA. Deaminase may convert cytosine to uracil and then UG mismatch is formed that is either repaired by UND or the DNA strand is broken but either way it can result in mutagenic alteration. The removal of uracil from viral RNA by host UNG is detrimental to the pathogen. ►DNA repair, ►glycosylases, ►immunoglobulins; Krokan HE et al 2001 *Progr Nucleic Acid Res Mol Biol* 68:365.

Uniformity Principle: ►Mendelian laws

UniGene: A database of human and other organisms' ESTs and sequences of known genes to assist in identifying those which belong to the same cluster and have similar functions. This collection is suitable for microarrays and large-scale study of gene expression. ►EST, ►locuslink/ENTREZ GENE; Schuler GD et al 1997 *J Mol Med* 75:694; Zhuo D et al 2001 *Genome Res* 11:904; <http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=unigene>; sets of transcript sequences: <http://www.ncbi.nlm.nih.gov/UniGene/build2.html>; transcriptome of various eukaryotic species: <http://www.ncbi.nlm.nih.gov/UniGene/>.

Unikont: ►bikont

Unilateral Incongruity: A special type of incompatibility when only the females of one of the related species are compatible with the males of the other species. In other words, it is a unidirectional compatibility. ►self-incompatibility; Bernacchi D, Tanksley SD 1997 *Genetics* 147:861.

Unimodal Distribution: Has only one major peak (see Fig. U5).

Figure U5. Unimodal distribution

Unineme: Refers to a single strand (e.g., of DNA or post-mitotic chromosome before the S phase).

Uninformative Mating: Does not shed light on the genetic constitution of the parents because it lacks clarity regarding linkage of the markers that may have poor penetrance or expressivity or both or the traits concerned are under polygenic control.

Uniparental Disomy (UPD): Both homologous chromosomes are inherited from only one of the parents in a diploid. UPD involves an epigenetic change like

imprinting. When the two chromosomes are identical the case is called *isodisomy*, if they are different it is known as *heterodisomy*. For e.g., in 10% of the Russel-Silver syndrome cases a 35 Mb segment at 7q31-ter is maternally inherited as an isodisome. Uniparental disomy may be caused by the loss of one chromosome in a trisomics or duplication of a monosome. In a female cystic fibrosis patient markers on chromosome 7 indicate non-paternal disomy (Spence JE et al 1988 *Amer J Hum Genet* 42:217). In human UPD acrocentric isochromosomes and Robertsonian translocations between non-homologous chromosomes predominate. ▶ [imprinting](#), ▶ [epigenesis](#), ▶ [nondisjunction](#), ▶ [trisomy](#), ▶ [monosomic](#), ▶ [isochromosome](#), ▶ [Robertsonian translocation](#), ▶ [hydantidiform mole](#); Kotzot D 2001 *J Med Genet* 38:497.

Uniparental Inheritance: In the absence of male transmission of plastids and mitochondria, the genetic material of these organelles is transmitted to the progeny only through the egg. Also, telochromosomes and large deletions can generally be transmitted only through the female, if transmitted at all. In some species of *Mytilus* (mussel) one set of mtDNA is preferentially transmitted through the female whereas the other set is inherited paternally (Kenchington E et al 2002 *Genetics* 161:1579). The latter phenomenon is *doubly uniparental inheritance*. ▶ [mtDNA](#), ▶ [ctDNA](#), ▶ [doubly uniparental inheritance](#), ▶ [paternal leakage](#), ▶ [mitochondrial genetics](#), ▶ [chloroplast genetics](#), ▶ [imprinting](#)

Unipolar Depression: Refers to periods of depression with generally debilitating consequences but usually last for a shorter duration. A single nucleotide replacement (Arg441→His) in the tryptophan hydroxylase-2, a rate-limiting step in serotonin biosynthesis, causes 80% loss in serotonin production and it may be one of the causes of unipolar depression (Zhang X et al 2005 *Neuron* 45:11). ▶ [bipolar mood changes](#), ▶ [affective disorders](#)

Uniporter: A transporter, which transports a type of molecule without coupling it to any other.

UniProt (universal protein resource): The most comprehensive information source on proteins from several resources. (See <http://www.uniprot.org>).

Unique DNA: DNA present in a single copy per genome. ▶ [singlet](#)

UniSTS: A marker information database, which is a unified non-redundant view of sequence-tagged sites (STS); it can be used for e-PCR. ▶ [STS](#), ▶ [e-PCR](#); <http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=unists>.

Unit Evolutionary Period (UEP): Refers to time in million years (MY) required for the fixation of 1% divergence in two initially identical nucleotide sequences.

Unitig: ▶ [scaffolds in genome sequencing](#), ▶ [U-unitig](#)

Univalent: Denotes an eukaryotic chromosome without a pair. In case the chromosomes in a hybrid are not sufficiently homologous, they may form univalents and their distribution to the poles in meiosis may be disorderly. The frequency of univalents may permit conclusions regarding the lack of relatedness of the parental forms (see Fig. U6). ▶ [triticale](#)

Figure U6. Hybrid of an octaploid ($2n = 56$) and hypoploid ($2n = 41$) hexaploid triticale. The female gamete contributed 28 and the male only 20 chromosomes. Therefore, there are 20 bivalents and 8 univalents in meiosis. Seven out of 8 univalents represent the *D* genome of wheat. Generally, the lagging univalents are not incorporated into the functional gametes because they fail to reach the poles. Usually, they divide belatedly. (Courtesy of Kiss Á 1966 *Z Pflanzenzücht* 55:309).

Universal Bases: The natural nucleoside of hypoxanthine or the synthetic 6-hydroxy- and 6-amino-5-azacytosine nucleosides or 1-(2'-deoxy- β -D-ribofuranosyl)-3-nitropyrrole may serve for modified nucleotides in recognition of G, T and U with equal efficiency for Watson-Crick pairing (see Fig. U7).

The latter maximizes stacking while minimizing hydrogen pairing without sterically disrupting the double helix. Some of the analogs lower, whereas others increase the melting temperature of the polynucleotides that contain them. These may be used to synthesize oligonucleotide probes and primers when the exact sequence needed cannot be inferred because of the redundancy of the genetic code. Oligonucleotides containing the 5-nitroindole base may be easily detected by an antibody. In SNIPs the mismatched base

Figure U7. Pairing of the bases T (thymine), C (cytosine), A (adenine) and G (guanine) with N^8 -(2'-deoxyribofuranoside) of 8-AZA-7-deazaadenine, a universal base.

can be identified easily. The addition of analogs to the 5' end may enhance the stability of the analog oligonucleotide on the chips. The presence of these universal bases may alter nucleic acid-protein interactions. When in an A:C mismatch 3-nitro-pyrrole replaced C the fidelity of ligation increased substantially. The incorporation of nitroazole analogs may increase the stability of triplex sequences. Klenow fragment polymerase inefficiently incorporated nitro-pyrrole derivatives and the analog generally terminated further chain extension. ►hydrogen pairing, ►probe, ►primer, ►DNA chips, ►azacytidine, ►PCR, ►SNIPs, ►sequence saturation mutagenesis; Loakes D 2001 Nucleic Acids Res 29:2437; Seela P, Debelak H 2000 Nucleic Acids Res 28:3224.

Universal Code: The majority of DNAs across the entire phylogenetic range use DNA codons in the same sense. Notable exceptions exist in the mitochondria and in a few species. ►genetic code; O'Sullivan JM et al 2001 Trends Genet 17:20.

Universal Donor: ►ABO blood group

Universal Recipient: ►ABO blood group

Universal Trees: Display the evolution of orthologous proteins across taxonomic boundaries. (See Brown JR et al 2001 Nature Genet 28:281).

Univoltine: Having one generation annually.

Unix: A multi-user, multi-tasking computer system for servers, desktops and laptops. (See <http://www.ee.surrey.ac.uk/Teaching/Unix/>).

Unnatural Amino Acids: These are not coded for by the natural genetic system. The amber suppressor tyrosyl-tRNA synthetase of *E. coli* can translate the suppressor codon as tyrosine in the bacterium. When the enzyme is expressed in *Saccharomyces cerevisiae* it can aminoacylate the tRNA_{CUA} but it does not aminoacylate any of the regular cytoplasmic tRNAs. The bacterial tRNA_{CUA} is transported into the yeast cytoplasm and participates efficiently in translation. Mutations can be selected, which under specific conditions can translate certain unnatural phenylalanine and tyrosine amino acid derivatives in prokaryotic and eukaryotic systems. Thus, by such a technology the classic 20-amino acid code can be expanded and the consequences of these unnatural amino acids on the proteins can be determined. The incorporation of unnatural amino acids into proteins requires a unique codon suppressor tRNA and the corresponding aminoacyl-tRNA synthetase. The specificity of the aminoacyl tRNA can be modified by mutations at the active site and selection of the enzyme, which can specifically acylate the tRNA with the unnatural amino acid but not the conventional amino acid. At present more than 30 unnatural amino acids can be added to proteins using the procedure (Turner JM et al 2006 Proc Natl Acad Sci USA 103:6483). Actually, >190 unnatural amino acids are available commercially and >90 unnatural backbone and side-chain analogs can be enzymatically charged to tRNA (Hartman MCT et al 2006 Proc Natl Acad Sci USA 103:4356). Using an appropriately designed frameshift suppressor, tRNAs with four-base anticodons can deliver simultaneously two or three unnatural amino acids in response to the

quadruplet codons CGGG and GGGU into a neuroreceptor of *Xenopus* oocytes. The frameshift suppressor effectively competes with an amber suppressor if delivered in excess (Rodriguez EA et al 2006 Proc Natl Acad Sci USA 103:8650). A genetically engineered ribosome, ribo-X, is more efficient at readthrough of amber codons with an attached unnatural amino acid, because of reduced affinity of the 30S ribosome for release factor RF-1 that is normally supposed to terminate the translation (Wang K et al 2007 Nature Biotechnol 25:770). ▶amino acids, ▶aminoacylation, ▶genetic code, ▶suppressor tRNA, ▶aminoacyl-tRNA synthetase, ▶selenocystein, ▶pyrrolysine, ▶orthogonal mRNAs; Chin JW et al 2003 Science 301:964; structural requirement in tRNA synthetase: Kobayashi T et al 2005 Proc Natl Acad Sci USA 102:1366; expanded genetic code: Wang W et al 2006 Annu Rev Biophys Biomol Struct 35:225; Liao J 2007 Biotechnol Progr 23:28.

Unnatural Bases: ▶modified bases, ▶base analogs

Unordered Tetrads: These tetrads do not contain the spores in a linear order as generated in the first and second meiotic divisions (see Fig. U8). In contrast to ordered tetrads, unordered tetrads require the presence of three genetic markers and two of them must be in

Figure U8. Unordered tetrad

different chromosomes to be able to calculate gene—centromere distances. Again—as in ordered tetrads—it is important to determine the frequencies of tetatype tetrads for at least three markers considered and for this p is designated as the tetatype frequency of say a and b , and q is the tetatype frequency of b and c , and similarly r is the tetatype frequency for a and c . The exchange frequency between a and its centromere = x , between b and its centromere = y , and between c and its centromere = z . Furthermore, the following three equations are needed:

$$\begin{aligned} p &= x + y - 3/2xy & q &= y + z - 3/2yz \\ r &= x + z - 3/xz \end{aligned}$$

The values, p , q and r being known, the unknown quantities, the recombination frequencies (x , y and z)

between the three genes and their centromeres can be determined by solving the three equations:

$$\begin{aligned} x &= 2/3 \left(1 \pm \sqrt{\frac{4 - 6p - 6r + 9pr}{4 - 6q}} \right), \\ y &= 2/3 \left(1 \pm \sqrt{\frac{4 - 6p - 6q + 9pq}{4 - 6r}} \right) \text{ and} \\ z &= 2/3 \left(1 \pm \sqrt{\frac{4 - 6q - 6r + 9qr}{4 - 6p}} \right). \end{aligned}$$

Once the recombination frequency between a gene and its centromere becomes available, the exchange frequencies between additional genes and their centromeres can also be calculated by the formula: $s = \frac{2(v-t)}{2-3t}$ where s = the unknown recombination frequency between marker d and its centromere, t = the known recombination frequency between gene e and its centromere, and v = the tetatype frequency for the unmapped gene d and the mapped gene e . ▶tetrad analysis; Emerson S 1963, p. 167 Methodology in Basic Genetics, Burdette, WJ, [Ed.] Holden-Day, San Francisco.

Unphased Diploid Population: The linkage phase of the heterozygotes is unknown.

Unrooted Evolutionary Trees: These do not indicate the initial split of the branching. ▶evolutionary tree; Steel M, McKenzie A 2001 Math Biosci 170:91.

Unsaturated Fatty Acid: This contains one or more double bonds. ▶Omega-3-fatty acids

UNSCARE: United Nations Committee on Effects of Atomic Radiation.

Unscheduled DNA Synthesis: The replication of the DNA is outside the normal S phase and this indicates a repair replication. The tests are generally carried out on cultured hepatocytes or fibroblasts exposed to certain treatment(s) and the incorporation of radioactive thymidine is monitored by either autoradiography or scintillation counting. The data are compared with concurrent controls that have not been exposed to any mutagen. Although the procedure appears attractive it is not very effective and practical for the identification of mutagens or carcinogens. ▶bioassay in genetic toxicology, ▶DNA polymerases; Zbinden G 1980 Arch Toxicol 46:139; Hoege C et al 2002 Nature [Lond] 419:135.

Unstable Genes: These have higher than average mutation rate. Usually instability is caused by the movement of insertion or transposable elements (see Fig. U9). Higher mutation rate may also be due to deficiency of genetic repair or defects in DNA

replication. ▶DNA repair, ▶insertional mutation, ▶transposable elements, ▶error in replication, ▶fractional mutation, ▶variegation, ▶genomere

Figure U9. Unstable genes

Unstructured Proteins: These lack three-dimensional (globular) structure in free state but may become structures upon binding to other macromolecules. The adaptability of their structure is an advantage in regulatory functions. ▶phosphorylation; Wright PE, Dyson HJ 1999 *J Mol Biol* 293:321; Iakoucheva LM et al 2004 *Nucleic Acids Res* 32:1037.

Unsupervised Learning: Identifies new, so far undetected, shared pattern(s) of sequences in macromolecules and determines the positive and negative representatives of the pattern(s). The information permits correlations between structure and function in languages as well as in proteins without direct human intervention in the details. ▶supervised learning, ▶support vector machine; Wallis G, Baddeley R 1997 *Neural Comput* 9:883; Hatzivassiloglou V et al 2001 *Bioinformatics* 17 Suppl 1:S97; Solan Z et al 2005 *Proc Natl Acad Sci USA* 102:11629.

Untoward Pregnancy: Pregnancy that terminates with congenital malformation or stillbirth or infant death within 14 days after delivery. ▶congenital

Untranslated Regions (UTR): These are the leader sequences upstream from the first methionine codon and the downstream sequences beyond the stop codon of the mRNA. The upstream and downstream regions include various control elements and at the 3' end in eukaryotes the polyadenylation signal is situated. The untranslated regions of the mRNA do not code for any amino acid sequence. The 3'-UTRs in RNAs control translation, the fate of germ line cells, life cycle, anterior-posterior axis of development, meiotic cycles by binding proteins similarly to the DNA binding proteins. The ENCODE project observed that most of the longer protein-coding transcripts differ only in their UTRs but the coding regions are shared. ▶upstream, ▶downstream, ▶stop codon, ▶polyadenylation, ▶ENCODE; Kuersten S, Goodwin EB 2003 *Nature Rev Genet* 4:626; eukaryotic regions: <http://www.ba.itb.cnr.it/UTR/>.

Unusual Bases: Refer to modified forms of the normal DNA or RNA bases; they may be common in tRNA. Their incorporation into the DNA may lead to base substitution mutations. Methylation of C and A nucleotides may lead to imprinting, transient genetic variations in expression and alteration of RFLP. DNA containing an unnatural base pair can be amplified and function as a template for the site-specific incorporation of base analog substrates into RNA via transcription. Base-pairing in such a case takes place by specific hydrophobic shape complementation between the bases, but lacks hydrogen-bonding interactions. In replication, this unnatural base pair exhibits high selectivity in combination with the usual triphosphates and modified triphosphates, gamma-amidotriphosphates, as substrates of 3' to 5' exonuclease-proficient DNA polymerases, allowing PCR amplification. In transcription, the unnatural base pair complementarity mediates the incorporation of these base substrates and their analogs, such as a biotinylated substrate, into RNA by T7 RNA polymerase (Hirao I et al 2006 *Nature Methods* 3:729). With this system, functional components can be site-specifically incorporated into a large RNA molecule. ▶tRNA, ▶RFLP, ▶imprinting, ▶methylation of DNA, ▶Bar, ▶modified bases; Barciszewski J et al 1999 *Mol Biol Rep* 26:231.

Unverricht-Lundborg Disease (EPM1): ▶myoclonic epilepsy

Unwindase: Refers to double-stranded RNA helicases that unwind in a single step the entire length of a molecule in an ATP-dependent process. ▶DexH, ▶NPH; Nishikura K 1992 *Ann NY Acad Sci* 660:240.

Unwinding Protein: Facilitates unwinding of a DNA double helix and stabilizing single strands. The nucleotide triphosphate (NTP)-dependent RNA helicases are required for unwinding of double-stranded RNA and replication of many pathogenic viruses. ▶DNA replication, ▶helicase; Dillingham MS et al 2001 *Proc Natl Acad Sci USA* 98:8381.

Unzipping of DNA: Refers to the separation of the double-stranded structure. Depending on the base composition, the threshold force required is about 12 pN (piconewton). One joule is the work done when a force of 1 N acts through a distance of 1 meter. ▶joule; Cocco S et al 2001 *Proc Natl Acad Sci USA* 98:8608.

uORF: Denotes upstream open reading frame which may play a regulatory role in protein synthesis.

UP Elements (upstream elements): In the DNA, (−40 to −150 sites from the initiation of transcription) are recognition sites for the α subunit of the prokaryotic RNA polymerase which boost (30 to 300-fold) the frequency of transcription initiation. The −46 to −38 element, 5'-AAAAAARNR-3'

stimulates transcription up to 170-fold, the -57 to -47 element, 5'-AWWWWT TTTT-3' stimulates transcription up to 16-fold (Estrem ST et al 1999 Genes & Develop 13:2134). [W = A or T, R = A or G, N = no single base pair is present in 70% of the population and no 2 bp make up 95% of the population]. The α subunit C-terminal domain and the σ subunit bind initially to the -35 sequence and in the final isomerization the downstream double helix is embedded in the β/β' jaws leading to the transcriptionally active complex (Sclavi B et al 2005 Proc Natl Acad Sci USA 102:4706). ►transcription factors, ►promoter, ► σ , ►FIS, ►CRP, ►RNA polymerase, ►isomerization of strands, ►gyrase, ►topoisomerase, ►triplex

Up-and-Down: The structural arrangement of helical protein bundles comparable to the meander of β -sheets. ►meander, ►protein structure

UPE: Refers to the upstream promoter element. ►promoter

UPGMA (unweighted pair group method with arithmetic means): These are formulas for determining evolutionary distances. ►transformed distance, ►evolutionary distance; Kim KI et al 2002 Animal Genet 33:19.

UPR (unfolded protein response): Regulates gene expression when the endoplasmic reticulum does not function properly. It may control chaperones, phospholipid biosynthesis, secretory pathways and degradation of proteins associated with the endoplasmic reticulum under stress or even without stress. ►endoplasmic reticulum, ►chaperones, ►unfolded protein response; Bertolotti A, Ron D 2001 J cell Sci 114:3207.

Upregulation: Refers to increasing activity by regulation. ►downregulation, ►regulation of gene activity

Upstream: This is in the direction of the 5' end of polynucleotides (DNA). ►downstream

Upstream Activation Sequence: ►UAS

Upstream Regulatory Sequence (USR): This is the regulatory element in the promoter region.

U

Uptag: ►bar code genetic

Uptake: Eukaryotic cells may incorporate nuclei, plastids and mitochondria, pseudovirions, plasmids, liposomes and various other macromolecules besides smaller organic and inorganic molecules. Viruses move from cell to cell through the plasmodesmata and through the vascular system of plants. Plant viruses generally encode a movement protein that modifies the plasmodesmata, binds to single-stranded nucleic acids and associates with the cytoskeleton and the endoplasmic reticulum. (See Tzfira T et al 2000 Annu Rev Microbiol 54:187).

Uptake, Selective: Inorganic or organic molecules are not taken up by a stochastic process but the uptake is regulated by special mechanisms. ►ion pumps, ►transformation, ►conjugation

Uracil: A pyrimidine base in RNA; 2,4-dioxypyrimidine, MW 112.09, soluble in warm water but insoluble in ethanol. ►pyrimidines

URE (ureidosuccinate utilization): Cytoplasmic proteins involved in nitrogen metabolism in yeast are responsible for the production of a protein analogous to prion. ►prion; Baxa U et al 2002 Proc Natl Acad Sci USA 99:5253.

Urea Cycle: Describes the formation of urea ($[\text{NH}_2]_2\text{CO}$) from amino acids and CO_2 ; ornithine is converted to citrulline which in turn is converted to arginine. The hydrolytic cleavage of arginine produces urea and regenerates ornithine and thus the cycle is complete. The urea cycle in the mitochondria secures homeostasis for ammonium with some independence of the nitrogen intake. The mutation in the ornithine transporter (encoded at 13q14) involves the symptoms of hyperornithinemia-hyperammonemia-homocitrullinuria syndrome. ►arginine, ►ornithine, ►citrulline carbamoylphosphate synthetase deficiency, ►amino transferase

Uredium: A uredospore producing sorus, a type of sporangium of fungi and protozoa (see Fig. U10). ►stem rust, ►sorus

Figure U10. Uredium

Uremia: Refers to urine in the blood caused by a variety of factors.

Ureotelic: Excreting urea. ►Urea (NH_2CONH_2), ►Urea cycle

Urethan ($\text{CH}_3\text{H}_7\text{NO}_2$): This is a toxic (lethal dose 2g/kg in rabbits) liquid (at 48–50 °C). It causes chromosomal breakage and mutation; it is also antineoplastic.

URF (unidentified reading frame): Capable of transcription (open) but the gene product has not been identified. ►[reading frame](#)

Uric Acid: A degradation product of xanthine and it is excreted in the urine (see Fig. [U11](#)). It is secreted in particularly high amounts in hyperuricemic individuals under dominant and polygenic control, as well as in glycogen storage diseases, HPRT deficiency and gout. Birds and reptiles normally excrete high amounts. ►[glycogen storage diseases](#), ►[gout](#), ►[HPRT](#), ►[Lesch-Nyhan syndrome](#), ►[xanthinuria](#)

Figure U11. Uric acid

Uricotelic: Excretes uric acid. ►[uric acid](#)

Uridine: Uracil + ribose, an RNA nucleoside. ►[pyrimidines](#)

Uridine Diphosphate Glucuronosyl Transferase: Encoded in human chromosome 2; this group of enzymes is glucuronate steroid hormones. ►[Crigler-Najjar syndrome](#)

Uridine Monophosphate Synthetase Deficiency (UMPS): ►[oroticaciduria](#)

Uridylate: Refers to the nucleotide of uracil. It contains uracil + ribose + phosphate.

URL (uniform resource locator): The generic name for an Internet resource, such as WWW page; Gopher menu (<http://www.sc.edu/bck2skol/fall/lesson12.html>), a file transfer protocol server, etc. ►[bookmarks](#)

URNA: This is a uridine-rich nuclear, non-coding RNA involved in transcript processing within the cell nucleus. (See Dye MJ et al 2007 Cold Spring Harbor Symp Quant Biol 71:275; Matera AG et al 2007 Nature Rev Mol Cell Biol 8:209).

21U-RNA: 21U-RNAs are precisely 21 nucleotides long, begin with a uridine 5'-monophosphate but are diverse in their remaining 20 nucleotides, and appear modified at their 3' terminal ribose. 21U-RNAs originate from more than 5,700 genomic loci dispersed in two broad regions of chromosome IV of *Caenorhabditis*—primarily between protein-coding genes or within their introns. These loci share a large upstream motif that enables accurate prediction of additional 21U-RNAs. The motif is conserved in other nematodes, presumably because of its importance for producing these diverse,

autonomously expressed, small RNAs (Ruby JG et al 2006 Cell 127:1193). ►[small RNA](#)

U-RNP: U-RNA associated with proteins involved in processing the primary transcripts of genes within the nucleus.

Urocortin: A neuropeptide similar to urotensin and corticotropin releasing factor. It elicits the synthesis adrenocorticotrophic hormone and is therefore involved in stress-related endocrine, autonomic and behavioral responses. ►[adrenocorticotropin](#), ►[urotensin](#), ►[corticotropin releasing factor](#); Parkes DG, May CN 2000 News Physiol Sci 15:264.

Urogenital: Denotes both the system of urine secretion and the reproductive organs.

Urogenital Adysplasia: Autosomal dominant failure to develop one or both kidneys, frequently coupled with wide set eyes, low set ears and other anomalies. The incidence among newborns may be as high as 4.5% and among adults 0.3%. ►[kidney disease](#)

Urokinase (uPA): A plasminogen activator. The urokinase receptor is a glycosyl-phosphatidyl-inositol-linked cell surface protein that regulates cell adhesion. It has been suggested that urokinase is a requirement for some cancerous growths. Some catechins (present in green teas) appear inhibitory to uPA. ►[plasminogen](#), ►[CAM](#), ►[intravasation](#), ►[anthrax](#); Andreassen PA et al 1997 Int J Cancer 72:1; Plesner T et al 1997 Stem Cells 15:398; crystal structure: Huai Q et al 2006 Science 311:656.

Uropathy: Refers to diseases of the urogenital system.

Urotensins: These are short bioreactive peptides of 41 (urotensin I) and 12 (urotensin II) amino acids, respectively. ►[urocortin](#); Lewis K et al 2001 Proc Natl Acad Sci USA 98:7570.

URS: These are upstream regulatory/repressing sequences which are the binding sites for various transcription factors. ►[promoter](#), ►[transcription factors](#), ►[regulation of gene activity](#), ►[UAS](#); Hanna-Rose W, Hansen U 1996 Trends Genet 12:229.

Urticaria, Familial Cold (Muckle-Wells syndrome, 1q44): Autosomal dominant disease is characterized by reoccurring, transient burning papules and macules on the skin, cold-sensitivity, and is frequently associated with progressive deafness and renal amyloidosis (fibrillary protein deposits in the kidneys). ►[cold hypersensitivity](#)

Use and Disuse: ►[Lamarckism](#)

Usher Syndrome (USH): The condition is hereditary yet the pattern of inheritance is quite variable although in most cases it is probably autosomal recessive. It is characterized by deafmutism, retinitis pigmentosa,

mental disabilities and ataxia. Three types of the syndrome are usually distinguished on the basis of the severity and onset of the disease. The prevalence is around $4 - 5 \times 10^{-5}$. USH1 has a pre-pubertal onset; seven loci are associated with it. About 75% of the afflicted individuals have a severe defect in the USH1B gene in human chromosome 11q13.5, encoding myosin VIIA. USH1A is in chromosome 14q32 (Heilig R et al 2003 Nature [Lond] 421:601). Other types of the disease all involving hearing deficit and some other anomalies have been reported: USH1D and DFNB12 (10q21-q22), USH1F (chr. 10q21-q22, protocadherin), USH1E (21q21) USH2A (1q41). USH1G encodes a scaffolding protein. USH1D encodes a type of cadherin (CDH23) that causes stereocilia disorganization in waltzing mouse with hearing deficit (Bolz H et al 2001 Nature Genet 27:108). A milder form has been assigned to 1q32. Myosin VIIA may be involved in the transport between the outer and inner layers of the photoreceptors of the eye. In type IIa form a 171.5 kDa protein is involved that has a laminin epidermal growth factor and fibronectin type III motifs pointing to the involvement of defects in cell adhesion. USH1C involves a defect in the PDZ domain (involving PSD-95, DLG and ZO-1 proteins) of harmonin. The PDZ modules interact with all other proteins concerned with signaling and the cytoskeleton. Deletions of the USH1C gene may lead to infantile hyperinsulinism, enteropathy (intestinal disease) and deafness. USH3 (3q21-q25) encodes a 120-amino acid protein concerned with recessive, progressive hearing loss and severe retinal degeneration. ▶retinitis pigmentosa, ▶ataxia, ▶deafmutism, ▶deafness, ▶waltzing mouse, ▶myosin, ▶cadherin, ▶hypoglycemia, ▶EGF, ▶laminin, ▶fibronectin, ▶CAM; Verpy E et al 2000 Nature Genet 26:51; Bolz H et al 2001 Nature Genetics 27:108; Bork JM et al 2001 Am J Hum Genet 68:26; Ahmed ZM et al 2001 Am J Hum Genet 69:25; Joensuu T et al 2001 Am J Hum Genet 69:673; Adato A et al 2005 Hum Mol Genet 14:347.

USM (ubiquitous somatic mutations): These are attributed to defects in DNA repair (mismatch repair) and in DNA replication. ▶DNA repair, ▶unstable genes

U-snRNP: A splicing factor of RNA transcript. ▶splicing, ▶spliceosome; Xue D et al 2000 EMBO J 19:1650.

USP (chromosome-specific unique sequence probes): Employ locus-specific fluorescent DNA sequences which are suitable for the identification of small deletions and duplications. ▶FISH, ▶chromosome painting, ▶WCPP, ▶telomeric probes

Ustilago maydis (n = 2): Basidiomycete that has been extensively used for meiotic and mitotic analysis of

recombination and for the isolation of biochemical mutations, etc. The 20.5-million base genome contains 6,902 protein-coding genes (see Fig. U12). Its pathogenicity is controlled by 12 clusters of genes encoding secreted proteins (Kämper J et al 2006 Nature [Lond] 444:97). This fungus causes the ear smut of maize. The haploid forms are non-pathogenic. Several other *Ustilago* species are pathogenic to other Gramineae. ▶fungal life cycles; Banuett F 1995 Annu Rev Genet 29:179.

Figure U12. *Ustilago* on maize ear

UTase (uridylyl transferase): Catalyzes the transfer of uridylyl group to the P_{II} regulatory subunit of adenylyl transferase (ATase), an enzyme which transfers an adenylyl group from ATP to a tyrosine-hydroxyl in glutamine synthetase. The complex ATase • P_{II}-uridylyl catalyzes phosphorolytic deadenylylation of glutamine synthetase. Glutamine synthetase is an enzyme involved in many functions. ▶glutamine synthetase, ▶glutamate dehydrogenase

UTE (untranslated exon): May play a role in alternative splicing of transcripts. ▶alternative splicing; Chen C et al 2002 Proc Natl Acad Sci USA 99:2930.

Uterine Cancer: Cancer of the uterus may be treated by anti-estrogens similarly to breast cancer. The response to tamoxifen is very limited, however. Cervical cancer usually does not respond to such treatment and surgery and radiation are used. ▶breast cancer

Uterus: The hollow female abdominal organ where the fertilized egg is embedded for the development of the embryo. The pear-shaped uterus (~5 × 7.5 cm in humans) is connected to the vagina through the narrow neck-like passage, the cervix, permitting the entry of the spermatozoa, to retain the conceptus and open to release the embryo at birth. The ovaries are connected to the uterus by the oviducts (see Fig. U13). The uterus is lined by endometrium that feeds the early embryo. Its outer layer is shed during menstruation and regenerated thereafter. When the blastocysts reach a state ready for implantation, the uterus becomes receptive under the influence of the ovarian steroid hormones—progesterone and oestrogen. Luteinizing hormone, secreted by the ovaries, is essential for ovulation and for the programming of progesterone and oestrogen. The duration of this oestrus cycle is about 4 days in mice and almost

a week in humans. ►gonads, ►ovary, ►blastocyst, ►oestrus, ►luteinizing hormone, ►fallopian tube, ►morsus diaboli, ►fertilization, ►embryogenesis in animals, ►menstruation, ►vagina, ►endometrium, ►tamoxifen, ►cervical cancer; Wang H, Dey SK 2006 Nature Rev Genet 7:185.

Figure U13. The abstract outline of the female reproductive tract; the red arrow indicates the path of the egg and the blue arrow indicates the direction of movement of the spermatozoa

Utility Index for Genetic Counseling: If the mother is heterozygous for a recessive disease allele d/D and other linked alleles (M_1/M_2), i.e., she is DM_1/dM_2 and the frequency of recombination between the two loci is r , half of her sons will be afflicted by the disease and $1-r$ frequency of M_2 sons is expected to express the disease (as long as penetrance and expressivity are high). A small r helps predictability. If her husband's genotype is DM_1 , among her M_1M_2 daughters $1-r$ will be a carrier of the recessive disease allele d but one must know for sure which of the codominant M alleles is syntenic with d . In the case of X linkage, for prediction on the basis of the M markers, the genetics counselor should know the genotype of the affected grandfather (dM_1 or dM_2). If the frequencies of the M_1 and M_2 markers is x_1 and x_2 , respectively and the grandfather is dM_2 , then the probability that the mother being informative for genetic counseling is $= 2x_1x_2$. Roychoudhury and Nei have described this as the *utility index of a polymorphic locus* for genetic counseling. If the grandfather has the recessive allele m and the grandmother is either MM or Mm , their heterozygous (Mm) daughter must have inherited the M allele maternally and the expected frequency of informative mothers is $(1-x)x$. In case both M and m grandfathers are considered, the utility index of the mother becomes: $(1-x^2)x$.

Genetic information about the mother can also be obtained from her children. In case the X-linked

disease gene deemed to be in coupling with another marker, the Bayesian probability for coupling is $(1-r)^2/[(1-r)^2 + r^2]$ and the probability for repulsion is $r^2/[(1-r)^2 + r^2]$ if the mother has already two afflicted sons. If the mother has both normal and afflicted sons: n_1 (DM_1), n_2 (DM_2), n_3 (dM_1) and n_4 (dM_2), the probability for coupling that she has 4 ($=n$) sons with the genotypes above is: $r^{n_2+n_3}(1-r)^{n_1+n_4}/2^n$; in case of repulsion the probability is: $r^{n_1+n_4}(1-r)^{n_2+n_3}/2^n$. The posterior probability that she is in coupling is $1/(1+\rho^\alpha)$ where $\rho = r/(1-r)$ and $\alpha = n_1 + n_4 - (n_2 + n_3)$, and in case $\alpha = 0$, the linked markers will not help in the prognosis. For repulsion, the probability is $1/(1+\rho^{-\alpha})$. The probability of the genotype of the next offspring depends on the tightness of linkage.

In the case of *autosomal dominant* disease in the presence of D , the disease is expected and both parents are informative. If the mother is M_1M_2 and the father is M_1M_1 and the recombination frequency between the M and the D loci is r , the probability that the offspring of M_1M_1 genotype will have D is $1-r$. DD homozygotes are very rare because their occurrence depends on the product of the frequency of the D gene, which is usually in the 10^{-5} range. In case there are multiple alleles at a locus, the total frequency of informative parents is

$$1 - \sum X_i^2 - (\sum X_i^2)^2 + \sum X_i^4.$$

In a mating of $(Dm/dM) \times (dM/dm)$, the offspring homozygous for m has a probability of $1-r$ to carry the dominant disease gene, D $1-r$ but the one with the dominant M phenotype is expected to be D at a frequency of $(1+r)/3$. If the affected parent D is heterozygous and the other parent is dd , the frequency of informative families is $2(1-x)x^4$. In case the mating is $(DdM_1M_2) \times (ddM_1M_2)$, the children are $n_1(DdM_1M_1)$, $n_2(DdM_1M_2)$, $n_3(ddM_1M_1)$ and $n_4(ddM_1M_2)$, respectively. The linkage phase can be estimated as discussed earlier for X linkage [coupling: $1/(1+\rho^\alpha)$, repulsion $1/(1+\rho^{-\alpha})$]. All children of parent DdM_1M_2 will be informative, except when the spouse is ddM_1M_2 and all the progeny will be heterozygous for the M locus but the probability that all children would be of such genetic constitution is $(0.5)^n$. The proportion of informative families when $n > 1$ is: $2x_1x_2(1 - 0.5^{n-1}x_1x_2)$. If there are multiple markers, the proportion of informative families (with x_i frequency of the i th allele) is:

$$2 \sum_{i < j} X_i X_j (1 - 0.5^{n-1} X_i X_j).$$

In the case of *autosomal recessive* diseases the calculation of the mathematical probabilities of informative families is more complex and biochemical or molecular (DNA) analyses are preferred.

►DNA fingerprinting, ►genetic counseling, ►counseling genetic, ►risk, ►paternity testing; Roychoudhury AK, Nei M 1988 Human Polymorphic Genes, Oxford University Press, New York.

UTP: Denotes uridine triphosphate (see Fig. U14).

U-Unitig: ►scaffolds in genome sequencing, ►unitig

UV: ►ultraviolet light, ►cyclobutane dimers

Uvomorulin (UM): A transmembrane glycoprotein, also known as E-cadherin. ►cadherins

UvrABC: An endonuclease complex of uvrA, uvrB and uvrC and these enzymes are involved in the excision of ultraviolet light-induced pyrimidine dimers. After the dimer is recognized, cuts are made on both sides of the dimer and thus the damaged area of about 12 nucleotides is excised. ►DNA repair, ►ABC excinucleases, ►excision repair

UV Spectrophotometry of Proteins: Prepare a series of dilutions (20 to 3,000 µg/mL) from a pure 3 mg/mL standard bovine serum albumin (BSA). Make a blank and a series of dilutions of the sample to be tested. Determine UV absorption at 280 nm. BSA, 3 mg/mL is expected to have an absorption of 1.98. Calibrate the sample relative to the standard. In case the absorptivity of the protein to be tested is known use the formula for the calculations (a_{280} = the absorption in the units of mg/mL per centimeter path b).

$$\frac{O.D_{280}}{a_{280} \times b}$$

Historical vignettes

“The attainment...of fundamental knowledge is usually of the utmost immeasurable practical importance in the end”.

HJ Muller 1916, quoted by Elof Carlson
(30 years later [in 1946] Muller received the Nobel Prize)

Priority has been of important concern to authors from the early days of genetics. In his book “A History of Genetics” (Harper & Row, New York, 1965) AH Sturtevant writes on p. 27:

In a letter received and published by Roberts, de Vries later stated that he had worked out the Mendelian scheme for himself, and was then led to Mendel’s paper by reading Bailey’s copy of Focke’s reference. In 1954, nineteen years after the death of de Vries, his student and successor Stomps reported the de Vries had told him that he learned of Mendel’s work through receiving a reprint of the 1866 paper from Beijerinck, with a letter saying that he might be interested in it. This reprint is still in the Amsterdam laboratory, as has been stated.

V

V Gene: Codes for the variable region of the antibody molecule.

V or V_{\max} : The maximal velocity of the reaction when the enzyme is saturated with substrate.

V-point: The progression of the cell cycle beyond this point (≈ 6 h before the S phase) requires no insulin but only IGF-1. ► [cell cycle](#), ► [insulin](#), ► [insulin-like growth factor](#)

Vaccines: A suspension of killed or attenuated pathogens or recombinant protein or DNA or capsular polysaccharides conjugated to a carrier protein for generating an immune defense system. The most successful vaccines (measles, mumps, rubella) are composed of antigens generated against disease-causing microorganisms and injected into the blood-stream to stimulate the development of circulating or serum antibodies (immunoglobulin G). More recently efforts have been made to develop vaccines that activate mucosal immunity. Membranes of the body, covering the gastrointestinal tract, the air-intake organs and the reproductive system are covered with mucosa. The aim of this procedure is to trap infectious agents at the port of entry. The mucosa can develop sufficient quantities of immunoglobulin A. These new vaccines may be orally delivered and do not have to be injected. Dendritic cells, which are most active in antigen presentation, can be targeted by microparticles conjugated with monoclonal antibodies. These can then reach the lymph nodes and stimulate both cytotoxic T cells as well naïve T cells and the enhanced immune response is proven by increased interferon- γ secretion (Kwon YJ et al 2005 Proc Natl Acad Sci USA 102:18264).

Some vaccines use live microorganisms that have been genetically engineered by removal of part of their genome so that they do not cause the disease yet promote the production of IgA and some also IgG (see Fig. [V1](#)). Other approaches include the introduction of the genes of cytotoxic lymphocyte epitopes into the cells. The presence of CpG oligonucleotide motifs in the vector plasmid appears to enhance the immunogenicity of DNA vaccination in humans. Genetically engineered vaccines may be produced in transgenic plants as well and they may eventually be edible. After infection by the lymphocytic choriomeningitis virus, mice may clear the LCMV and gain

lifelong immunity to reinfection because the DNA containing LCMV sequences is transcribed in the animals represents a new type of DNA vaccination. Prophylactic vaccination against retroviral diseases is hampered by the apparent poor immune reaction against these agents. Bovine leukemia virus (BLV), which produces a relative paucity of variants that confound the cytotoxic T cells (CTL) can, however, be vaccinated successfully by using a viral glycoprotein, gp51 epitope. Several poxviruses, modified vaccinia virus, replication-defective adenovirus, etc., appear to boost the DNA vaccines' effectiveness for primed CD $^{+}$ T cells. Some adjuvants (alum, monophosphoryl lipidA, oil/water emulsion, etc.) have also revealed beneficial effects in some cases. A new approach to vaccination is the use of antibodies against cytokines that accumulate in inflamed or tumor tissues (Zagury D et al 2001 Proc Natl Acad Sci USA 98:8024). Synthetic polysaccharide antigen conjugated with protein (tetanus toxoid) yields an effective vaccine at an economically low cost (Verez-Bencomo V et al 2004 Science 305:522). The availability of completely sequenced genomes of viral and bacterial pathogens permits vaccine design by bioinformatics seeking out unique, potentially antigenic sequences without growing the target organisms. This approach is known as *reverse vaccinology* (Mora M et al 2003 Drug Discovery Today 10:459). The post-exposure prophylactic vaccines are administered after acute infections by tetanus, diphtheria and rabies. The latter type of vaccination follows a somewhat different logic than the prophylactic type (and it is somewhat controversial) yet its efficacy is corroborated by medical practice. The effectiveness of the vaccines may be boosted by the increase in CD4 and CD8 T lymphocyte activity and helps to reduce the proliferation of the pathogen (Autran B et al 2004 Science 305:205). When administered with various interleukins and other chemokines, their effectiveness may be enhanced. After successful vaccination, the T cell may clonally expand in 7–10 days and antigen-specific CD8 $^{+}$ T cells may increase 100,000-fold and differentiate into effector helper T (TH) cells and cytotoxic killer cells (NK). After the removal of the antigen the number of the antigen-specific cells contract (in 2–4 weeks) and a fraction of the T cells differentiate into memory cells for long-term protection. In germinal centers and plasma foci short-lived antibody cells and longer lasting memory B cells are formed. Once an antigen presenting dendritic cell locates an antigen-specific T cell by immunological synapse, various proteins (TCR-MHC, CD2, CD8 LFA-1, PKC, Lck, Fyn, CD4, CD45) are recruited within the central SMAC region and this further strengthens the immunological response. The number of T cells may be stimulated to increase 100 to

Figure V1. Construction of a recombinant vaccinia genome (LacZ bacterial reporter, P11 and P7.5 are promoters, TK: thymidine kinase fragments, pUC plasmid provides origin of replication and ampicillin resistance [β -lactamase])

1,000-fold within a few days. The innate immune system helps to direct the activated T cells to the sites of pathogen invasion. B1 B cells produce small amounts of immunoglobulin M (IgM) and immunoglobulin A (IgA) even in the absence of a specific antigen. High affinity B cells are produced by affinity maturation. These B cells may migrate to the plasma foci, induce strong germinal center responses and affinity maturation and probably generate long-life memory B cells. Antigen presenting cells may take up attenuated bacterial pathogens (*Listeria monocytogenes*), which do not replicate and are rapidly destroyed. After destroying them, the phagolysosomes release the antigens for endogenous processing and presentation and stimulate CD8⁺ effector T cells. The intracellular replication deficient vaccine strain is rapidly cleared from normal and immunocompromised animals but antigen-specific T cells are stimulated and the animals acquire resistance to the wild type bacteria in a directed manner (Bouwer HGA et al 2006 Proc Natl Acad Sci USA 103:5102).

Some vaccines are highly effective and long-lasting, but vaccination against many other infections demands substantial improvements (Pulendran B, Ahmed R 2006 Cell 124:849). Vaccinia Virus: Closely related to small pox (variola) and cowpox viruses. It does not occur in nature and is found in the laboratory only where these two viruses are handled. Thus, it appears to have been somehow derived from variola and cowpox. Vaccinia vectors have been used to express antigens of unrelated pathogens (AIDS virus, hepatitis B) and employ them for immunization. The virus contains a DNA genome of about 190 kbp with nearly 260 potential open reading frames and around 200 bp telomeric sequences (see Fig. V2). These viruses direct replication and transcription in the cell cytoplasm by viral-encoded enzymes. Therefore, insertion of the viral genome by recombination is not a major threat. Vaccinia virus appears to be relatively safe yet periodically (every 10 years) laboratory workers should be vaccinated against it and the handling should be under containment level 2. Vaccinia virus with a deletion in the serpin gene and expressing IFN- γ replicated to high titer in vivo were avirulent in both immunocompetent and immunocompromised

Figure V2. Vaccinia virus of $\sim 360 \times 270 \times 250$ nm (Redrawn after Cyrklaff, M. et al. 2005 Proc. Natl. Acad. Sci. USA 102:2772)

animals, indicating its potential for the production of efficacious and safe vectors against smallpox and other diseases (Legrand FA et al 2005 Proc Natl Acad Sci USA 102:2940). Vaccinia vectors appear to be effective against some tumors and metastasis when injected directly into the neoplasia. Vaccinia virus infects productively the majority of mammalian and avian cells but the Chinese hamster ovary cells are not infected and the replication of the virus may not be completed in primary lymphocytes or macrophages. For infection, the virus requires the presence of the E3L vaccinia protein or a homolog of it. These proteins facilitate viral binding to Z-DNA. Vaccinia protein F11L interacts with RhoA and blocks downstream effectors and RhoA signaling is required for both vaccinia morphogenesis and virus-induced cell motility (Valderrama F et al 2006 Science 311:377).

Mouse antibody constructed from the Chimpanzee Fab domain completed with the human $\gamma 1$ heavy chain constant region provided an effective response to vaccinia virus B5 envelope protein. It protected mice from intranasal challenge against the virus even 2 days after exposure. The chimpanzee/human mAb provides effective prophylaxis and immunotherapy of smallpox (Chen Z et al 2006 Proc Natl Acad Sci USA 103:1882). ▶immunization, ▶immunotherapy, ▶Fab, ▶antibody, ▶Xgal, ▶ β -galactosidase, ▶bio-hazards, ▶serpins, ▶interferon, ▶Rho; Kim Y-G et al 2003 Proc Natl Acad Sci USA 100:6974, diagram of the genome redrawn after Chakrabarti S et al 1985 Mol Cell Biol 5:3403.

Vacuoles: These vesicles within plant and fungal cells are filled with various substances (nutrients, products of secondary metabolism, enzymes, crystals, solutes). Vacuoles may occupy minimal space in meristematic cells of plants whereas in older cells they occupy up to 90% of the cell inner volume. The elastic tonoplast membrane surrounds the vacuoles and permits a change in their size. They may regulate the osmotic pressure of the cytosol by releasing smaller molecules or polymerizing them as needed to maintain a constant value in the cytoplasm. Vacuoles also

Figure V3. Large vacuoles in a plant cell (bottom) and an oblong nucleus with nucleolus (top)

regulate pH by a similar balancing action. They supply the cells with storage nutrients, hydrolytic enzymes, anthocyanin pigments, and in some cases various toxic substances such as tannins, phenolics and alkaloids. Vacuoles are inherited by the partition of the cytoplasm but if a particular cell becomes vacuole free its progeny may generate them de novo. ▶lysosomes, ▶cells, ▶membrane fusion; Klionsky DJ, Ohsumi Y 1999 Annu Rev Cell Dev Biol 15:1; Rojo E et al 2001 Developmental Cell 1:303; Weisman LS 2003 Annu Rev Genet 37:435.

Vagility: Refers to the ability of organisms to disperse in a natural habitat, it is thus a factor of speciation and survival.

Vagina: The female organ of copulation beginning at the vulva and extending to the cervix of the uterus. *Vaginismus* is an involuntary painful contraction of the vaginal muscles and may cause severe pain especially in intercourse. An autosomal recessive condition of vaginal atresia (absence of vagina) is known. In general, the term denotes an anatomical sheath. The vaginal epithelium may harbor several species of bacteria even under completely healthy conditions and without any symptoms; the most common of such bacteria are various lactobacilli (Hyman RW et al 2005 Proc Natl Acad Sci USA 102:7952). ▶clitoris, ▶fallopian tube, ▶ovary, ▶egg, ▶migraine, ▶uterus, ▶vulvovaginitis, ▶microbiome

Vaginal Plug: After successful copulation in mice, part of the male ejaculate forms a vaginal plug that closes the vagina for 16–24 hours and in some strains even for a few days. The presence of the plug reveals to the breeder the success of the mating. ▶mating plug

Valence (valency): The valence of an antibody indicates the number of antigen-binding sites. In chemistry, it indicates the number of covalent bonds an atom can form and it is also called oxidation number, e.g., O^{2-} or Na^{+} or Ca^{2+} .

Validation: Refers to the confirmation of experimental results or working hypotheses by repeated tests (proof of principle). It is the process of determining the degree to which a model is an accurate representation of real life facts. Validation is important as one depends increasingly on predictions by computer models. Validation of a target may be based on the expression of genes in the pathway, the use of microRNA or RNAi blocks or mutation or knockout in the system. ▶proof-of-concept; Benson JD et al 2006 Nature [Lond] 441:451.

Valine Biosynthesis: ▶isoleucine-valine biosynthetic pathway

Valinemia: ▶hypervalinemia

Valyl tRNA Synthetase (VARS): This is encoded in human chromosome 9. VARS charge tRNA^{Val} by the amino acid valine. ▶aminoacyl-tRNA synthetase

VAMOS (variability modulation system): Denotes the expression of *reactivity* of females, measured on the basis of the percentage of sterility in daughters in hybrid dysgenesis. Reactivity is modulated by various factors such as temperature, age of the females over generations and inhibitors of DNA synthesis and ionizing radiation. ▶hybrid dysgenesis

VAMP (vesicle associated membrane protein, synaptobrevin): This is a synaptic protein. ▶syntaxin, ▶synaptobrevin, ▶SNARE

Van Buchem Disease (17q11.2): A form of osteosclerosis. ▶sclerosteosis; Loots GG et al 2005 Genome Res 15:928.

Van der Waals Force: Refers to weak, short-range attraction between non-polar (hydrophobic) molecules.

Van der Woude Syndrome: A dominant, human chromosome 1q32-q41-located cleft lip and palate syndrome. ▶cleft palate, ▶harelip, ▶epithelial cell, ▶popliteal pterygium; Schutte BC et al 2000 Genome Res 10:81.

Van Gogh, Vincent (1853–1890): The famous Dutch painter may have suffered from intermittent porphyria and periods of deep depression (see Fig. V4). The beautiful *Starry Night* painting was attributed to a hallucinatory spell experienced during a bout of bipolar disorder and heavy drinking of absinth. The *Drosophila* gene named *vangogh* modulates the expression of *wingless*. The mammalian homolog

(*Vangl2*) of this *Drosophila* gene encodes a four-transmembrane PDZ protein, which along with *Scrb1* (scribble) regulates a signaling pathway involved in planar orientation of the epithelium and the stereocilia. ▶depression, ▶bipolar mood disorder, ▶PDZ, ▶stereocilia, ▶porphyria, ▶wingless; Montcouquiol M et al 2003 Nature [Lond] 423:173; <http://www.med.wayne.edu/elab/vangogh/MainIndex.htm>.

Vancomycin (C₆₆H₇₅Cl₂N₉O₂₄): An extremely potent glycopeptide antibiotic effective against gram-positive bacteria by blocking the cross-linking of adjacent peptidoglycan strands by peptide bonds in bacterial cell wall synthesis (see Fig. V5). It also inhibits transglycosylation, which connects the existing glycan strands. In recent years *Streptococcus pneumoniae*, responsible for pneumonia, bacterial meningitis and ear infection, as well as several *Enterococcus* species have acquired tolerance or resistance to this antibiotic. Vancomycin tolerance is due to mutation in the Vancomycin signal transduction sensor kinase (VncS). Upon autophosphorylation in the presence of ATP, VncS-P is generated. As a consequence the Vancomycin sensor regulator (VncR) is phosphorylated to VncR-P and the defense genes (resistance to the infection) of the cells are turned off. In Vancomycin (and some other antibiotic) sensitive strains VncS dephosphorylates VncR. The efficacy of Vancomycin as an antibiotic is due to its binding to the D-Ala—D-Ala moiety of the bacterial peptidoglycan precursors and thereby hindering growth of the cell wall. In the resistant strains, the dipeptide is replaced by the depsipeptide D-Ala—D-Lac reducing sensitivity to the antibiotic by three orders of magnitude. (Depsipeptide is a member of the bicyclic peptide class of histone deacetylase [HDAC] inhibitors that was first isolated as a fermentation product from *Chromobacterium violaceum*). The level of resistance depends on the number of peptidoglycan precursor molecules that carry this replacement. Vancomycin resistance may be overcome by chlorobiphenyl vancomycin derivatives, which interact with penicillin-binding protein-1 (PBP1b) although they do not bind the enzyme (Chen L et al 2003 Proc Natl Acad Sci USA 100:5658). IfD-Ala—D-Lac is selectively disrupted by small molecules (prolinol derivatives) (see Fig. V6) sensitivity to Vancomycin is restored. Reengineering Vancomycin for dual D-Ala-D-Ala and D-Ala-D-Lac binding can effectively counter resistance of the bacteria (Crowley BM, Boger DL 2006 J Am Chem Soc 128:2885). A neoglycosylation procedure increases efficacy 40-fold (Griffith BR et al 2007 J Am Chem Soc 129:150). ▶antibiotics, ▶tolerance of antibiotics, ▶antibiotic resistance, ▶non-ribosomal peptide; Chiosis G, Boneca IG 2001 Science 293:1484; Eggert US et al 2001 Science 294:361; Reynolds AM et al 1996 J Infect 32:11.

Vanilla (*Vanilla planifolia*): This is a tropical spice tree;
 $2n = 2x = 32$.

Vanillin ($C_8H_8O_3$): A flavoring agent and an analytical reagent. It is an antimutagen, anticlastogen, anticarcinogen and an inhibitor of non-homologous end-joining and DNA-PK. ▶clastogen, ▶NHEJ, ▶DNA-PK; Durant S, Karran P 2003 Nucleic Acids Res 31:5501.

Váradi-Papp Syndrome: ▶orofacial-digital syndrome V

Variability: Denotes the condition of being able or apt to vary.

Variable: A condition or treatment that may be replaced by the experimenter or that may change during the study. The pre-analytical variables are known or unknown factors that may be present before or arise during the analysis. In clinical studies the pre-analytical variables may contribute to serious errors in the evaluation. In experimental research the variables may be under more stringent control than in observational studies.

Variable Number Tandem Repeats: ▶VNTR

Variable Regions: These regions of the antibody are situated at the amino end of both light and heavy chains, and this region determines antibody specificity and antigen binding. ▶immunoglobulins, ▶antibody

Variable Surface Glycoprotein: ▶Trypanosoma

Variance: The mean of the squared deviations of the variates from the mean of the variates:

$$V = \sum [(x - \bar{x})^2] / n - 1 \quad \text{where } x \text{ are the variates and } \bar{x} \text{ is the mean of the variates and } n \text{ is the number of variates (individuals).}$$

▶variate, ▶invariance, ▶standard deviation, ▶standard error, ▶analysis of variance, ▶intraclass correlation, ▶genetic variance

Variance Analysis: ▶analysis of variance

Variant: Refers to a cell or individual different from the standard type.

Variant Detector Array (VDA): Uses oligonucleotide labeled probes to locate/identify particular genes in microarrays. ▶microarray hybridization, ▶oligo-labeling probes

Variate: A variable quantity measured in a sample of a population.

Variation: Can be *continuous* and individual measurements do not fall into discrete classes, e.g., traits determined by polygenic systems. In the case of *discontinuous* variation the measurements can be classified into distinct classes such as the qualitative traits (black and white [no gray]) in a segregating population (see Fig. V7). ▶variance, ▶genetic variance, ▶continuous variation, ▶discontinuous variation, ▶SNIP; Crawford DC et al 2005 Annu Rev Genomics Hum Genet 6:287.

Figure V7. Variation

Variation, Mathematical: This is illustrated by an example. How can a cell express 3 different receptors of a pool of 10 receptors? The solution is $\frac{10 \times 9 \times 8}{1 \times 2 \times 3} = 120$. ▶combination

Varicella-Zoster Virus: This member of the Herpes virus family causes chickenpox and shingles. Vaccination effectively reduces mortality due to chickenpox but its effect on shingles is still unknown. The Oka vaccine strain is a live attenuated virus that is routinely administered to about 40 million children in the United States and Europe to prevent chickenpox. It is effective and safe but occasionally produces a rash. The vaccine virus has accumulated mutations at more than 30 loci during its attenuation and after administration, but the rashes are not explained by their reversion, unlike complications reported in the case of other viral vaccines. The host genotype and immune status also affect the extent of response to the vaccine (Quinlivan ML et al 2007 Proc Natl Acad Sci USA 104:208). Insulin degrading enzyme (IDE) is a cellular receptor of the virus and mediates cell-to-cell spread (Li Q et al 2006 Cell 127:305). ▶herpes, ▶shingles, ▶chickenpox

Variegation: Refers to sector formation or mosaicism of the somatic cells due a number of different mechanisms such as nondisjunction, somatic mutation, segregation of organelles (chloroplasts) deletion and disease (see Figs. V8 and V9). Heterochromatin may cause variegation of genes in its close vicinity by transient modulation of the exposure of the DNA to transcription factors. In *Drosophila* more than 15 genes act as suppressors of variegation (*Su[va]*). ▶uniparental inheritance, ▶lyonization, ▶broken tulip, ▶transposable elements, ▶position effect, ▶piebaldism, ▶spotting, ▶mitotic recombination,

▶nondisjunction, ▶developmental-regulator effect variegation, ▶heterochromatin; Ahmad K, Henikoff S 2001 Cell 104:839; Sjiv IS et al 2007 Nature [Lond] 447:399.

Figure V8. Mosaicism in cattle

Figure V9. Variegation in a plant leaf

Variety: Refers to an organism of a distinct form or function. ▶cultivar, ▶cultigen

Variogram: A plot of genetic distance relative to geographic distance. ▶genetic distance

Variola: This is the technical term for smallpox virus, pox virus, vaccinia and biological weapons.

Variolation: The earliest form of vaccination known at least by the sixth century. Infective material from the smallpox lesions was transferred to healthy individuals to provide resistance against the disease with an expectation of not more than ~4% fatality versus 20–30% from natural infection. ▶vaccine, ▶pox virus

Varkud Plasmid: ▶*Neurospora* mitochondrial plasmids

Vas Deferens: An excretory channel of the testis connected to the ejaculatory duct of the sperm. ▶CBAVD, ▶P2X

Vascular Cell Adhesion Molecule (VCAM): ▶metastasis

Vascular Diseases: ▶cardiovascular diseases

Vascular Endothelial Growth Factors (VEGF): These are required for vasculogenesis and are particularly active in some tumor tissues to provide the necessary blood supply for proliferation. VEGFs depend on their appropriate (VEGFRs) integrin cell adhesion receptors (De S 2005 Proc Natl Acad Sci USA 102:7589). The receptor (VEGFR2) is a tyrosine kinase. In human

primary lymphedema (Milroy disease) VEGFR-3 tyrosine kinase activity is deficient. Mouse mutants with a defect in receptor-3 of VEGF die of cardiovascular failure (9.5 d) before birth. VEGF has been considered as a potential benefit in case heart disease damages the blood vessels. The peptide QK binding to the interface of VEGF receptor can induce endothelial cell proliferation and blood capillary formation. Therefore, QK has biomedical (therapeutic and diagnostic) potential (D'Andrea LD et al 2005 Proc Natl Acad Sci USA 102:14215). VEGF can also cause vascular permeability and the accumulation of fibrin barrier around tumors and wounds. The leakage can reduce metastasis of tumors and can induce obstruction and necrosis of blood vessels (infarction). VEGF not only promotes tumor growth and reduces metastasis, but it may also facilitate atherosclerosis (Weis SM & Cheresh DA 2005 Nature [Lond] 437:497). The endocrine-gland-derived endothelial growth factor (EG-VEGF) is selectively expressed only in the ovary and other steroid-producing tissues (testis, adrenal and placental tissues). ▶angiogenesis, ▶Flk-1, ▶Flt-1, ▶neuropilin, ▶tyrosine kinase, ▶VEGF, ▶polyposis hamartomatous, ▶KDR, ▶Peg-3, ▶angiopoietin, ▶atherosclerosis, ▶hypoxia, ▶wound healing, ▶lymphedema, ▶phospholipase, ▶macular degeneration; Ferrara N 1999 J Mol Med 77:527; Bellamy WT et al 1999 Cancer Res 59:728; LeCouter J et al 2001 Nature [Lond] 412:877; Niethammer AG et al 2002 Nature Med 8:1369; <http://www.researchvgef.com>.

Vascular Targeting: For the development and maintenance of tumors, an ample supply of blood is a requisite. The monoclonal antibody to bFGF and VEGF may block the required angiogenesis factors. Similarly, integrins (CD51/CD61) are also required for angiogenesis and they can be interfered with by their cognate monoclonal antibodies. Anti-endoglin antibody, especially with conjugated ricin, may lead to anti-tumor effects. ▶angiogenesis, ▶angiostatin, ▶endostatin, ▶ADEPT, ▶VEGF, ▶FGF, ▶integrin, ▶endoglin

Vascular Tissue: In plants, this includes the xylem, the phloem, the (pro)cambium and the surrounding fibrous parenchyma. In animals the blood vessels are the primary vascular tissue. ▶phloem, ▶xylem, ▶cambium, ▶parenchyma, ▶proteoglycan

Vascularization: Refers to the development of veins and other vessels. ▶vasculogenesis

Vasculogenesis: Refers to the differentiation of mesodermal cells into hemangioblasts. ▶hemangioblast, ▶blood formation, ▶angiogenesis, ▶CXCR

Vasculopathy: Vascular retinopathy, cerebretinal vasculopathy, endotheliopathy with retinopathy, nephropathy and stroke all map to 3p21.1-p21.3.

The abnormalities of the vascular system cause Raynaud's disease, migraine, retinal vein impairment, visual disease, renal disease, neurological problems and possibly premature death. ▶Raynaud's disease; Ophoff RA et al 2001 Am J Hum Genet 69:447.

Vasectomy: The surgical removal of the vas deferens (ductus deferens), the excretory channel of the semen. It is a method of fertility control for males. ▶birth control drugs; Sandlow J et al 2001 Fertil Steril 75:544; Weiske WH 2001 Andrologia 33:125.

Vasodilator: Causes expansion of (blood) vessels.

Vasopressin: ▶antidiuretic hormone, ▶oxytocin (see Fig. V10)

Figure V10. Human vasopressin

VASP: A profilin-binding protein. ▶profilin

VAT: Denotes variant antigen type. ▶Trypanosoma

V-ATPases: These are vascular ATPases in control of ionic homeostasis. ▶APPase, ▶homeostasis

Vaults: These are large (42 × 75 nm, 12.9 MDa) predominantly cytoplasmic ribonuclein particles present across phylogenetic ranges. The mammalian vaults include the vault poly(A)DP-ribose polymerase, telomerase associated protein 1 and one or more non-translated RNAs (Poderycki MJ et al 2005 Nucleic Acids Res 33:893). Vaults are involved in detoxification and many cellular and developmental processes (Gopinath SCB et al 2005 Nucleic Acids Res 33:4874). (See Stephen AG et al 2001 J Biol Chem 276:23217).

Vav Oncogene: Found in human chromosome 19p13.2-p12, and appears to be GDP→GTP exchange factor requiring tyrosine phosphorylation. It regulates lymphocyte development and activation. ▶oncogenes, ▶B lymphocytes, ▶T cell receptor

vBNS (very high-speed Backbone Network Service): This is a computer network linking five supercomputer centers to facilitate fast scientific communication and remote control by the use of special equipment.

vCJD: A variant of the Creutzfeldt-Jakob disease, a possible contagious form of the mad cow disease; it infects humans as well, especially those homozygous for codon 129 methionine of the prion. ▶Creutzfeldt-Jakob disease, ▶encephalopathies, ▶prion

VCP (vasoline containing protein): Involved in lipid metabolism. ▶T cell receptor

V(D)J (variable[diversity]junction): Sequences in immunoglobulins where antibody diversity is generated by recombination at the RSS (recombinational signal sequence) sites. Several factors are important for V(D)J recombination: DNA-dependent protein kinase, Artemis, CRCC4 and ligase IV. The recombination may show tissue/organ specificity. ►immunoglobulins, ►T cell receptor, ►RSS, ►RAG, ►Artemis, ►DNA-PK, ►CRCC, ►ligase DNA, ►non-homologous end-joining; Gellert M 1992 Annu Rev Genet 26:425; Gellert M 1997 Adv Immunol 64:39; Bassing CH et al 2002 Cell 109:S45; Dai Y et al 2003 Proc Natl Acad Sci USA 100:2462; Xiong N et al 2004 Proc Natl Acad Sci USA 101:260.

VDR (vitamin D3 receptors): Receptors that control homeostasis, growth and differentiation. They preferentially bind to response elements of direct repeats, palindromes and inverted palindromes of hexameric core-binding domains, particularly well when they are spaced by three nucleotides. They can dimerize with 3,5,3'-triiodothyronine, a thyroid hormone receptor that can direct sensitivity of ligands for transactivation. ►vitamin D, ►transactivator, ►hormone response elements

Vector: Generally an insect or other organism transmitting parasites and/or pathogens. It also refers to any gene carrier derived from plasmids, viruses or produced synthetically such as liposomes or polyethylene particle driven by motor proteins along the microtubules. ►vectors, ►vectorette, ►vector cassette, ►liposome; Suh J et al 2003 Proc Natl Acad Sci USA 100:3878.

Vector, Algebraic: ►matrix algebra

Vector Cassette: A transformation construct carrying all essential elements (including reporter genes, selectable marker, replicator, etc.), and it can be used for the insertion of different DNA sequences. ►vectors, ►reporter gene, ►transformation, ►knockout, ►targeting genes

Vectorette: A short DNA sequence serving as a specific linker-primer for PCR amplification. It generally contains an inner, non-complementary sequence (bubble), flanked by two short pieces of duplex DNA (see Fig. V11). The 5' end may be either blunt or complementary to a restriction site, depending on the restriction enzyme used to digest the DNA. An overhang may prevent ligation of the 3' end. ►polymerase chain reaction, ►amplification, ►linker, ►primer, ►ligase, ►blunt end, ►overhang, ►restriction enzyme, ►splinkerette; Eggert H et al 1998 Genetics 149:1427; Devon RS et al 1995 Nucleic Acids Res 23:1644.

Figure V11. Vectorette

Vectors: These molecular genetic constructs are generally circular plasmids that can introduce exogenous genetic material into prokaryotic and eukaryotic cells. They may be *cloning vectors* that only replicate the DNA according to the plasmid replicon. The *expression vectors* carry genes complete with all the elements required for expression (promoter, structural gene, termination signals, etc.). *Gene fusion vectors* do not have promoters and the expression of the transferred gene is contingent on fusion with a host cell promoter. *Shuttle vectors* can carry the DNA among different hosts (such as *E. coli* and COS cells, *Agrobacterium* and plants). All vectors must have at least a replicator site, selectable marker(s) and mechanisms for the introduction of parts of their sequences into the host genetic material. ►cloning vectors, ►cosmids, ►phagemids, ►fosmids, ►ColE1, ►plasmovirus, ►yeast vectors, ►viral vectors, ►excision vectors, ►plasmids, ►transposable elements, ►NOMAD, ►BAC, ►BIBAC, ►YAC, ►HAC, ►PAC, ►transcriptional gene fusion vector, ►translational gene fusion vector, ►targeting vector, ►polyethyleneimine, ►pBR322, ►pUC vectors, ►transposon vector, ►liposomes, ►nanoparticles, ►cancer gene therapy, ►RetroTet-Art vector, ►polyplexes; vector database: <http://seq.yeastgenome.org/vectordb/>.

Vectors for Pathogens: See human pathogen vectors: <http://www.vectorbase.org/>.

VEGA (vertebrate genome annotation): A central depository for manual annotation of different vertebrate (human, mouse zebrafish) finished genome sequences. ►annotation of the genome; <http://vega.sanger.ac.uk/index.html>.

Vegetal Pole: Refers to the lower end of the animal egg where the yolk is concentrated. The opposite end of the egg is known as the animal pole. After fertilization the yolk moves to the central position and becomes the starting site of the differentiation of axes (anterior-posterior, dorsal-ventral, median-lateral) of the embryo. ►morphogenesis *Drosophila*, ►pole cell

Vegetative Cell: Involved in metabolism but not in sexual reproduction. ►gametogenesis in plants

Vegetative Hybrids: ►graft hybrids

Vegetative Incompatibility: ►fungal incompatibility

Vegetative Nucleus (macronucleus): ▶*Paramecium*,
▶tube nucleus

Vegetative Petite: ▶petite colony mutants

Vegetative Reproduction: Commonly observed in many species of plants (grafting, rooting) and lower organisms that use fission for propagation. The advantage of this type of reproduction is that the progeny forms a genetically homogeneous clone unless or until mutation takes place. ▶somatic embryogenesis, ▶grafting, ▶regeneration, ▶clone, ▶tissue culture

Vegetative State: Denotes asexual, unconscious, non-replicating, non-infectious, etc., depending on the context.

VEGF: Smooth muscle cells synthesize vascular endothelial growth factor, which is somewhat related to PDGF. The VEGF genes are divided among eight exons and by alternative splicing three different proteins are produced. It may enhance the growth of new blood vessels. FLT-1 is one of the VEGF receptors. ▶signal transduction, ▶PDGF, ▶vascular endothelial growth factor, ▶neuropilin, ▶angiopoietin, ▶vascular targeting

Vehicle: ▶vectors

Velans: ▶*gaudens*

Velocardiofacial Syndrome (VCFS): A heart and face, kidney, parathyroid and thymus defect caused by deletion in human chromosome 22q11. The gene most commonly affected is UFD1-l (ubiquitin fusion degradation; 22q11.2). ▶DiGeorge syndrome, ▶face/heart defects, ▶claudin, ▶tight junction, ▶schizophrenia, ▶deletion 22q11.2

VENA (plural venae, adj. venous): A vein that carries blood towards the heart.

Veneering of Antibody: Refers to the generation of a humanized antibody where some of the surface regions of the mouse antibody framework are replaced by human sequences in order to reduce immunogenicity. ▶antibody, ▶humanized antibody

Venn Diagrams: Data are represented by circles or ovals according to their common features, overlapping functions or exclusion (see Fig. V12). The three circles generate seven ($2^3 - 1$) areas that may be shaded or otherwise marked. Such diagrams may represent interactions of proteins or interactions among environmental effects.

Figure V12. Venn diagram

Venom: A (highly) toxic secretion of some serpents and insects. Some types of venoms have medical applications, e.g., for hemostasis. ▶hemostasis, ▶mast cells; toxin database: <http://ntrc.tamuk.edu/cgi-bin/serpentarium/snake.query>.

Venous Malformation (VM): This is caused by mutation at loci 1p21-p22 and 9p21. VM can occur in any tissue but is most common in the skin and muscle; it causes pain and bleeding, and even death at times.

Vent: A DNA polymerase extracted from *Thermococcus litoralis*. ▶recursive PCR

Ventral (from the Latin venter meaning abdomen): This is related to the position on the side opposite to the back.

Ventricular: An adjective that means belonging to a ventriculus (a cavity such as in the heart).

Venture: Variable number repeating elements (40 to >150) of 14–15 nucleotides, rich in guanine. The shorter VENTR alleles are associated with susceptibility to insulin-dependent diabetes mellitus (IDDM) but one of the long repeats ($14 \times 50 = 700$ nucleotides) appears to be protective against IDDM. ▶diabetes mellitus, ▶imprinting, ▶VNTR

Venules: These are small vessels that collect blood from the capillary veins.

Venus: A yellow derivative (YFP) of the green fluorescent protein (GFP). ▶aequorin

Venus Mirror: ▶pedigree, ▶female (see Fig. V13)

Figure V13. Venus mirror

Vermiculite: A commercial silicate medium to grow plants under greenhouse conditions.

Vermilion Eye Color of Insects: This is controlled by the *v* locus of *Drosophila* encoding tryptophan pyrrolase, an enzyme that converts tryptophan to formylkynurenin. The recessive vermilion eye color is actually bright scarlet because the brown ommochrome is not formed. The *v* eye discs when transplanted into normal tissues develop wild-type eye color. ►animal pigments, ►ommochromes, ►tryptophan

Vernalization: Some biannual or winter annual species of plants have a low temperature requirement for the induction and completion of the bolting and flowering stage of development. This need can be satisfied in spring planting by exposing the germinating seeds to near freezing temperatures for a genetically determined and variable period. It is also known as yarowization (in Russian yarowie kchleba means spring cereal). In *Arabidopsis*, the *FLC* is one of the loci to repress vernalization response. The other vernalization gene *FRIGIDA* (*FRI*) has been cloned. *VRN2* is a nuclear zinc finger protein that mediates the level of *FLC*. The *VRN/VIN* proteins deacetylate methylated histones H3K27me and H3K9me during vernalization-induced epigenetic silencing of the *FLC* (Mylne JS et al 2006 Proc Natl Acad Sci USA 103:5012). The *LHP1* (like heterochromatin protein) also assists in the maintenance of epigenetic silencing of the *FLC*. The *VRN1* gene of the A genome of wheat has also been cloned (Yan L et al 2003 Proc Natl Acad Sci USA 100:6263). Vernalization in cereals is controlled by MADS box transcription factors (Trevaskis B et al 2003 Proc Natl Acad Sci USA 100:13099). Apparently, low temperature and other gene products modulate the level of its transcript supposedly by demethylation of specific DNA sites. ►photoperiodism, ►photomorphogenesis, ►floral induction, ►histones; Reeves PH, Coupland G 2001 Plant Physiol 126:1085; Gendall AR et al 2001 Cell 107:525; Macknight R et al 2002 Plant Cell 14:877; Sung S, Amasino RM 2004 Nature [Lond] 426:159; Bastow R et al 2004 Nature [Lond] 426:164; Henderson IR et al 2003 Annu Rev Genet 37:371; molecular mechanisms: Sung S, Amasino RM 2005 Annu Rev Plant Biol 56:491.

Versenes (EDTA): These widely used laboratory chelating agents may cause chromosome breakage at higher concentrations (see Fig. V14). ►EDTA

Figure V14. EDTA

Vertebrates: These are animals with a spinal column (chordates) such as fishes, amphibians, reptiles, birds and mammals. (See VEGA for genomes vertebrate browser: <http://genome.ucsc.edu/>; <http://vega.sanger.ac.uk/index.html>).

Vertex (plural: vertices; node): ►networks

Vertical Resistance: The host plant is resistant to a specific race of the pathogenic microorganism.

Vertical Transmission: ►transmission

Very Low Density Lipoprotein: ►VLDL

Vesicles: These are membrane-surrounded sacs in the cell, generally performing storage and transport functions.

Vesicular Stomatitis Virus (VSV): A negative-strand RNA virus of 11,161 nucleotides, enclosed by a nucleocapsid (N). N is a 35-turn helix within the membrane-surrounded oval particles. There is a transmembrane G protein on the surface of the virion for binding cell surface receptors, required for infection. VSV viruses can be engineered into useful genetic vectors. An oncolytic variant is involved in antitumor activity and at the same time establishes an antiviral state that protects against toxicity in healthy cells (Bell JC et al 2002 Curr Gene Ther 2:243). ►CO₂ sensitivity, ►viral vectors, ►lentiviruses

Veterinary Medicine: ►databases; <http://netvet.wustl.edu/vetmed/health.htm>.

Veto Cell: This recognizes T cells and inactivates them. ►immune suppression; Reich-Zeliger S et al 2000 Immunity 13:507.

Vg-1: A protein that sends signals in animals to develop head and other nearby organs.

VG5Q: 4,049 bp DNA tract (chromosome 5) with a 2,145 ORF encoding 714 amino acids responsible for susceptibility to the Kippel-Trenauney syndrome. ►ORF, ►Kippel-Trenauney syndrome

VHL: ►von Hippel-Lindau syndrome

Viability: Refers to the ability to survive; this is a property of organisms depending on genetic, developmental and environmental factors. A normal human fetus may become viable outside the womb after its weight reaches about 500 g and around 20 weeks after gestation. The viability of a mutant is often expressed as the survival rate relative to the wild type.

Vibrio cholerae: Cause of cholera (see Fig. V15). The toxin is encoded in a filamentous phage (CTX φ) and the same extracellular protein secretion pathway that facilitates the horizontal spread of the phage, releases it. The integration of this virus requires host recombinase XerC and XerD. It takes place at a 28 bp

Figure V15. Diagram of *Vibrio cholerae*

site (*difI*) in bacterium chromosome 1. The single-stranded phage genome forms a hairpin structure and thus creates a recombination site for XerCD. XerC mediates a single pair of strand exchanges and integration at *difI* (Val M-E et al 2005 Mol Cell 19:559). *Vibrio* contains two chromosomes ($\sim 2.9 \times 10^6$ and $\sim 1.1 \times 10^6$ bp) encoding 2770 and 1115 ORF, respectively (see Fig. V16). The major virulence factor, CT and the toxin-coregulated, TCP are in the longer chromosome. The bacterium also contains a pathogenicity island (VPI) which apparently does not have a viral origin. The integron island involved in gene integration and dissemination is in the smaller chromosome. Chitin, present in the natural aquatic environment of the pathogen due to the shedding of crustacean exoskeleton, induces natural competence for transformation (Meibom KL et al 2005 Science 310:1824). Virstatin inhibits the expression of cholera toxin and the toxin coregulated pilus of the bacterium and protects mice from intestinal colonization (see Fig. V17) (Hung DT et al 2005 Science 310:670). Several members of the *Vibrios* are pathogenic and their genomes have been sequenced (Ruby EB et al 2005 Proc Natl Acad Sci USA 102:3004). ▶[cholera toxin](#); Heidelberg J et al 2000 Nature [Lond] 406:477; transcriptome: Xu Q et al 2003 Proc Natl Acad Sci USA 100:1286.

Figure V16. *Vibrio vulnificus*, saltwater parasite (Courtesy of CDC Public Health Image Library)

Figure V17. Virstatin

Vicariance: The occurrence of a species in a habitat other than expected or a function not expected by an organ.

Vicia faba: ▶[broad bean](#), $2x = 2n = 12$; its large chromosomes are well suited for cytological study. With the exception of the two largest chromosomes, the rest are acrocentric (see Fig. V18) (Courtesy of Dr. A. Sparrow). ▶[favism](#), ▶[vicin](#)

Figure V18. *Vicia faba*

Vicine: An alkaloid produced by *Vicia sativa* (vetch) may be the source of this cyanoalanine toxin which is especially hazardous for people and animals on a low sulphur diet. ▶[favism](#)

VIGS (virus induced gene silencing): Infecting viruses may silence the host plant genes as well as transgenes in plants may silence viral genes by the mechanism of RNAi. ▶[RNAi](#); Fagard M, Vaucheret H 2000 Plant Mol Biol 43:285; Voinnet O 2005 Nature Rev Genet 6:206.

Villus: Refers to vesicular projections on a membrane (see Fig. V19). The amniotic villi, near the end of the umbilical cord, are sampled for genetic examination during prenatal amniocentesis. The intestinal villi facilitate food absorption and their structure may be affected by intestinal cancer. ▶[amniocentesis](#)

Figure V19. Intestinal villi with blood vessels inside

Vimentin: A constituent of the filament network extending through the cytoplasm of eukaryotic cells. ▶[intermediate filaments](#), ▶[aggresome](#); Perez-Martinez C et al 2001 J Comp Pathol 124:70; Mor-Vaknin N et al 2003 Nature Cell Biol 5:59.

Vinblastine and Vincristine: These are antineoplastic alkaloids (interfere with microtubules and the cytoskeleton) from the shrub *Vinca rosea*. (See Fig. V20, ►microtubule, ►cytoskeleton; Gigant B et al 2005 Nature [Lond] 435:519).

Figure V20. *Vinca rosea*

Vinculin: A protein binding α -actinin, talin, paxillin, tensin, actin filaments and phospholipids; it also mediates the assembly of the cytoskeleton. (See mentioned items under separate entries, ►adhesion; Kálmán M, Szabó A 2001 Exp Brain Res 139:426; crystal structure of human vinculin: Borgon RA et al 2004 Structure 12:1189).

Violent Behavior: In humans, impulsive aggression has been attributed to reduced levels of 5-hydroxyindole-3-acetic acid in the cerebrospinal fluid and a nonsense mutation in MAOA enzyme results in aggressive behavior in a kindred. ►MAOA, ►behavior in humans

VIP16: A herpes simplex virus-encoded protein; it is a potent activator that controls the transcription of immediate early viral genes through interaction with the host cell factors. It is used for studies of molecular interaction with promoters and transcription factors.

VIR Genes: ►virulence genes *Agrobacterium*

VirA: Denotes agrobacterial kinase phosphorylating the product of virulence gene *VirG*.

Viral Budding: ►budding

Viral Cancer: ►cancer, ►oncogene

Viral Capsid: ►capsid; <http://viperd.b.scripps.edu/>.

Viral Encephalitis: Caused by neurotropic flaviviruses such as the Japanese encephalitis virus and the West Nile virus. Targeting a common domain of the envelope protein by short hairpin or RNAi delivered to the brain of mice by lentiviral vector secured complete protection against the disease (Kumar P et al

2006 PLoS Med 3(4):e96). ►RNAi, ►West Nile virus, ►lentiviruses

Viral Envelope: A protein-lipid coat of viruses. ►virus

Viral Ghost: Refers to empty viral capsids, without their own genetic material but they can be filled with DNA and become a genetic vector. ►transformation genetic, ►generalized transduction

Viral Oncogene: ►v-oncogene

Viral Vectors: These are *in vitro* genetically modified viral DNA (e.g., adenovirus, SV40, bovine papilloma, Epstein-Barr, BK viruses and Baculovirus [Polyhedrosis] virus), containing non-viral genes to be introduced into eukaryotic cells. A minimal viral vector contains only the replicational origin of the virus and the packaging signals but the other viral genes involving replication, virion structure and pathogenicity sites are removed. The removed viral DNA or RNA is replaced by a cassette of transgenes required for experimental purposes. *Autonomous stable viral vectors* have also been constructed that replicate in the cytoplasm. In order to prevent destruction of the cells, their copy number is limited by introducing copy number regulators. From the *bovine papilloma virus* (BPV) autonomous (episomal) and shuttle vectors have been constructed that maintain low (10–30) copies in the cytoplasm. The *shuttle vectors* can be rescued from the mammalian cells and can propagate various protein genes in another cell depending on a number of intrinsic and extrinsic factors. The *Epstein—Barr virus* (EBV) vector can be propagated in the cytoplasm of various types of mammalian cells at low copy number (2–4) and is suitable for the study of gene expression, regulatory proteins, etc. It can also be maintained in the nucleus of, e.g., B lymphocytes. The vector has up to 35 kb carrying capacity and can be rescued. The *BK* (baby kidney) *virus* has been advantageously used for human cells. Truncated retroviral HIV vectors (may not be able to recombine and reconstitute pathogenic forms) may be useful because they can be introduced into non-dividing cells. Lentivirus vectors can also pass into non-dividing cells such as hepatocytes, hematopoietic stem cells and neurons, in contrast to the most widely used mouse leukemia retrovirus (MuLV) vectors, which require DNA replication for integration. For human applications, *replication-deficient retroviral* vectors can accommodate 9 kb exogenous DNA and they are generally used in *ex vivo* studies. *Adenovirus vector* can carry 7.5 kb DNA and can be taken up by the cell, by a specific virus receptor and the $\alpha_v\beta_3$ or $\alpha_v\beta_5$ surface integrins. The adenoviral, herpes simplex, vaccinia and the autonomous parvovirus vectors are not integrated into the human genome and therefore do not lead to permanent genetic change

and the treatment has to be reapplied periodically (in weeks or months). The *adeno-associated virus* can integrate into the chromosomes in dividing cells but it is episomal in stationary stage cells. Most of the current vectors may cause inflammation because of antivector cellular immunity. The *Baculovirus (Polyhedrosis) virus* is used as a vector for insect cells. The targeting of viral vectors to specific tissues can be increased by genetically engineering into the envelope protein a special receptor for a target ligand, e.g., inserting erythropoietin into the Moloney murine leukemia retrovirus or adding an integrin sequence to the avian retrovirus envelope. The vesicular stomatitis virus (VSV) and the gibbon ape leukemia retrovirus (GALV) offer some target specificity but they form only 10^7 to 10^9 cell forming units (CFU)/mL and therefore all the target cells of the body cannot be reached. In order to target the vector to particular cell type the envelope protein of the virus must be so modified that it would recognize the target cell membrane receptor. In order to pass the membrane and move into the cell, the envelope protein—receptor complex must undergo a conformational change. The modified envelope protein, however, may not form an effective complex resulting in very low level of passing of the vector into the target cell. New technology (ligands specific for fibronectin and collagen of the cell matrix) may facilitate the enrichment of the vector in the extracellular matrix of the host cell facilitating a more effective uptake. *Non-viral vector*, organically modified silica (ORMOSIL) after appropriate treatment can bind the DNA and effectively deliver it to neural stem cells of the brain (Bharali DJ et al 2005 Proc Natl Acad Sci USA 102:11539). ▶virus, ▶vectors genetic, ▶parvoviruses, ▶vaccinia virus, ▶retroviral vectors, ▶Bellophage, ▶shuttle vector, ▶HIV, ▶lenti-viruses, ▶episomal vector, ▶adenovirus, ▶adeno-associated virus, ▶herpes, ▶plasmid rescue, ▶gene therapy, ▶erythropoietin, ▶ex vivo, ▶microinjection, ▶biolistic transformation, ▶liposomes, ▶transfection, ▶transformation genetic, ▶packaging cell line, ▶bio-hazards, ▶laboratory safety, ▶self-deleting vector, ▶packaging cell lines; Pfeifer A, Verma IM 2001, pp 353. In: Knipe DM, Howley PM (Eds.) *Fundamental Virology*. Lippincott Williams & Wilkins, Philadelphia, Pennsylvania; Porcellini A Blasi AD 2004 *Methods Mol Biol* 259:155; <http://www.brc.riken.jp/lab/dna/rvd/>.

Viremia: Refers to viruses in the blood.

Virgin: Refers to an individual who has not been mated or has not had prior sexual intercourse. In *Drosophila* the females can store the sperm received during prior mating and, therefore, the paternal identity can be determined only if virgin females are used.

Virgin T Cell: ▶immune response

Virile: An adjective for having the characteristics of an (adult) male, masculine.

Virino Hypothesis: This suggests that prions are caused by small nucleic acid-containing agents. ▶prion; Dickinson AG, Outram GW 1988 Ciba Found Symp, London 135:63.

Virion: A complete virus particle (coat and genetic material).

Virion RNA: Refers to cytomegalovirus/herpes virus encoded transcripts which are packaged within the virion and delivered to the host cell to assure their immediate expression after infection.

Virioplasm (virus factory): An intercellular compartment associated with the replication of some viruses.

Viroceptors: These are parts of the viral attack mechanisms directed against the host immune system. They mimic the cell receptors and tie up cytokines and chemokines that are destined to stimulate the immune defense and weaken the antibody production. ▶anti-body, ▶immune system, ▶interferons; Upton C et al 1991 *Virology* 184:370.

Viroid: A non-encapsidated RNA (ca. 1.2×10^5 daltons) which is capable of autonomous replication and (plant) pathogenesis, such as the potato spindle tuber viroid. Viroids are single-stranded, circular or linear RNA molecules with extensive intramolecular complementarity. These agents are localized in the nuclei of plants and do not seem to occur in animals although it was earlier assumed that prions were viroids. They are probably the smallest nucleic acid agents causing infectious diseases. (See Elena SF et al 2001 *J Mol Evol* 53(2):155; Rezaian MA 1999 *Curr Issues Mol Biol* 1:13; viruses and virions: <http://www.ncbi.nlm.nih.gov/genomes/VIRUSES/viruses.html>; <http://www.dpvweb.net/>).

Virosomes: These are liposomes with associated viral proteins and are expected to be used as vehicles for gene therapy. ▶liposome; Yomemitsu Y et al 1997 *Gene Ther* 4:631.

Virtual: This has the same properties as the real but it is not real; it is an imaginary concept. ▶digital gene, ▶genetics digital

Virtual Reality Training: Medical students learn surgery on three-dimensional models rather than on patients.

Virulence: Determines or indicates the infectivity or pathogenicity of an organism. It has recently been discovered that several bacterial species of different structure and functions acquired a shared

mechanism for virulence. About 15–20 protein genes with relatively low G-C contents (below 40%) are assembled in a “pathogenicity island” of either the bacterial chromosome or in a plasmid. These genes encode the molecular machinery (Type III virulence) to produce and transmit the bacterial toxins to their target. Inflammatory responses of the host fight *Shigella* bacteria. The O antigen on the surface of the lipopolysaccharide coat protects the bacteria. Glycosylation of this antigen enhances type III secretion, aids the injection of the toxin and contributes to serotype divergence (West NP et al 2005 Science 307:1313). In *Salmonella* species a 65–100 kb plasmid carries the genes required for systemic infection. A *Yersinia* effector protein (Yopj), a cysteine protease, specifically blocks the host signal transduction system at MAPKK. Yopj-related proteins occur in other bacterial pathogens of animals and plants. ►neurovirulence, ►signal transduction, ►avirulence, ►SAR, ►host-pathogen relations, ►pathogenicity island, ►secretion systems, ►*Shigella*, ►*Yersinia*; Mahan MJ et al 2000 Annu Rev Genet 34:139; Cotter PA, DiRita VJ 2000 Annu Rev Microbiol 54:519; bacterial virulence factor database: <http://www.mgc.ac.cn/VFs/>.

Virulence Genes of *Agrobacterium*: The Ti plasmid carries—in an about 35 kb DNA—major (*A*, *B*, *C*, *D*, *E*) and minor (*F*, *H*) virulence genes that mediate the process of infection and T-DNA transfer. The *VirA* gene codes for a single protein that is a transmembrane receptor. Its N-terminal periplasmic region responds to sugars and pH whereas the periplasmic loop between the two membrane layers responds to phenolic compounds (e.g., acetosyringone, secreted by the wounded plant tissues). This substance plays an important role in the induction of the cascade of all *Vir* genes although *VirA* itself is constitutive yet it is modulated by several factors. The C-terminus of *VirA* protein is autophosphorylated. *VirG* also codes for a single protein, a transcriptional regulator. For expression, it requires phosphorylation by *VirA*. *VirG* regulates by feedback the phosphate metabolism, mediated by *VirA*, and these two genes together are involved in conjugational transfer. The *VirB* operon encoding 11 proteins is also a conjugational mediator. The *VirB* complex is assembled at the cell pole and has an essential role in targeting the plant cell. *VirB7* to *VirB10* are minimally required for the formation of the pole *VirB* complex (Judd PK et al 2005 Proc Natl Acad Sci USA 102:11498). *VirB1* is a lysozyme-like protein. *VirB4* serves as a docking protein, along with other proteins, for strand transfer during infection (Middleton R et al 2005 Proc Natl Acad Sci USA 102:1685). *VirC* determines the host range and the C1 protein binds to the *overdrive* repeats near the right border of some octopine plasmids. The *VirD*

genes are responsible for four polypeptides. *VirD1* is a topoisomerase, *VirD2* is an endonuclease; in addition, this locus codes for a binding protein and a pilot protein guiding the T-DNA to the plant chromosome. *VirD2* interacts with the TATA box-binding protein and a nuclear protein kinase of plants (Bakó L et al 2003 Proc Natl Acad Sci USA 100:10108). *VirD4*, *VirB4* and *VirB11* also perform an ATPase function. *VirE2* codes for a binding protein, which coats the T-strand, mediates the transfer of single strand DNA into the plant nucleus (Zupan JR et al 1996 Proc Natl Acad Sci USA 93:2392). For stable transformation, viral protein 1 (VIP1) interacts with host cell H2A histone (Li J et al 2005 Proc Natl Acad Sci USA 102:57330). *VirF* probably encodes an extracellular protein that regulates *Vir* functions. *VirH* product may metabolize plant phenolics. Nopaline plasmids contain the gene *tzs* (trans-zeatin secretion) and *pin* (plant inducible) *F* loci. The chromosomal virulence loci (*ChvA*, *ChvB*, *Chv*, *pse*) are involved in the production of bacterial surface polysaccharides. Chromosomal genes *cbg*, *pgl*, when present, may enhance virulence. A single-stranded T-DNA complexed with proteins is transferred to the plant cells. Plant proteins are also involved in the transformation process (Tzfira T, Citovsky V 2002 Trends Cell Biol 12:121). ►*Agrobacterium*, ►Ti plasmid, ►T-DNA, ►overdrive, ►transformation genetic, ►crown gall, ►CRAFT, ►MPF; Winans SC et al 1999, p. 289. In: Kaper JB, Hacker J (Eds.) Pathogenicity Islands and Other Mobile Virulence Elements. Amer Soc Microbiol Washington, DC; Dumas F et al 2001 Proc Natl Acad Sci USA 98:485; Christie PJ et al 2005 Annu Rev Microbiol 59:451.

Virulent: In general, this is the poisonous form of prokaryotes. The virulent bacteriophages do not have the prophage life style and after reproduction they destroy the host bacteria by lysis. ►prophage, ►lysis

Virus: This is a small particle containing either double- or single-stranded DNA or RNA as genetic material. A generalized structure is diagrammed here; the architecture of viruses shows great variations from icosahedral to filamentous forms (see Fig. V21).

Figure V21. Generalized diagram of a viral structure

Viruses are the ultimate parasites because they lack any element of the metabolic machinery and are totally dependent on the host for assistance to express their genes. They are generally so small in size (15–200 nm) that light microscopy cannot reveal them, except the pox viruses which may be up to 450 nm in length. There are about 1,500 virus species. Bacterial, animal and plant viruses exist. The majority of plant viruses have single-stranded RNA genetic material but a few have double-stranded DNA, e.g., CaMO. Viruses have attracted new interest in nanotechnology as biological platforms, as vehicles for delivery into cells, for encapsulation of organic and inorganic molecules, etc. (Douglas T, Young M 2006 *Science* 312:873). ► **animal viruses**, ► **herpes**, ► **acquired immunodeficiency**, ► **plant viruses**, ► **bacteriophages**, ► **oncogenic viruses**, ► **retroviruses**, ► **cauliflower mosaic virus**, ► **mimivirus**, ► **TMV**, ► **nanotechnology**; Whittaker GR et al 2000 *Annu Rev Cell Dev Biol* 16: 627; for a chronology of virology: see Oldstone MBA, Levine AJ 2000 *Cell* 100:139; Sharp PM 2002 *Cell* 108:305; Virus Particle Explorer: <http://viperdb.scripps.edu/>; virus genome and protein sequence bioinformatics: <http://athena.bioc.uvic.ca/>; viral genomes: <http://gibv.genes.nig.ac.jp/>; <http://www.ncbi.nlm.nih.gov/genomes/VIRUSES/viruses.html>; http://www.biochem.ucl.ac.uk/bsm/virus_database/VIDA.html; plant viruses and viroids: <http://www.dpvweb.net/>.

Virus, Computer: A deliberately generated destructive program that can be spread through borrowed computer disks as well as network services. The damage to the files can be usually prevented by the use of continuously updated virus monitoring and eliminating programs.

Virus Hybrid: When the 2b gene of cucumber mosaic RNA virus is replaced by its homolog of tomato, virulence of the interspecific hybrid virus increases. ► **vaccinia virus**

Virus Morphology: ► **development**, ► **T4**, ► **lambda phage**, ► **retroviruses**

Virus Receptors: These are cell surface proteins that mediate viral entry into the host cell. The proteins can be cell adhesion molecules (CXCR4, CD4, dystroglycan, integrins, ICAM, major histocompatibility antigens, etc.), extracellular matrix proteins (heparan sulfate glycoaminoglycan, sialic acid derivatives) and complement control proteins (CD46, CD55), aminopeptidase-N, lipoprotein receptors, coxsackie virus and adenoviral receptors (CAR1), etc. Some receptors may serve several different viruses and some viruses can take advantage of more than one type of receptor. Single amino acid replacements in

the receptor either abolish or facilitate the uptake of the virus. (See Baranowski E et al 2001 *Science* 292:1102; Bomsel M, Alfsen A 2003 *Nature Rev Mol Cell Biol* 4:57).

Virus Reconstitution: ► **reconstituted virus**

Virus Resistance: The Fv and Rfv genes of mouse provide resistance against mouse leukemia (Friend virus) by encoding a retroviral envelope protein or the viral gag (group specific antigen). In the latter case the Fv gene product blocks the entry of the virus into the nucleus or these proteins may exercise a dominant negative effect on the virus that happens to be there. Introducing into the plant genome tobacco mosaic virus coat protein genes restricts the virulence of the virus in normally susceptible plants. ► **CRISPR**

Virus Transport to the Cell Nucleus: This is mediated by GAG matrix associated protein (MA) and the VPR gene product in the case of HIV. MA includes a nuclear localization sequence (NSL) and a signal targeting the cell membrane. When the NLS is phosphorylated, the MA becomes part of the pre-integration complex. Further phosphorylation detaches the MA from the membrane. ► **acquired immunodeficiency**, ► **nuclear localization sequence**; Bell P et al 2001 *J Virol* 75:7683.

Virus-Free Plants: Plants regenerated under axenic conditions from apical meristems are generally free of virus disease until they are reinfected. Plants so obtained are commercially useful for the production of virus-free seed stocks. Antisense RNA constructs may render plants virus resistant. (See Hammond J, Kamo KK 1995 *Mol Plant Microbe Interact* 8:674).

Virus-like Particles (VLP): These are artificial constructs of a viral protein capsid enclosing a core particle passenger. Such protein cage structures have shown increasing promise as therapeutic and diagnostic vectors, imaging agents, and as templates and microreactors for advanced nanomaterials synthesis. This type of biomimetic self-organization can combine the natural characteristics of virus capsids with the exquisite physical properties of nanoparticles. The principle challenges for nanoparticle delivery include limited lifetime in body fluids, nanoparticle transduction across the cellular membrane, avoidance of the exocytotic pathways and target specificity. A gold core functionalized with a coating of carboxylated polyethylene glycol (PEG) can allow efficient assembly of VLPs (Sun J et al 2007 *Proc Natl Acad Sci USA* 104:1354).

Virusoid: 300–400 nucleotide long RNAs, pathogenic to plants and accompany other plant viruses. ► **viroid**

Viscosity: The internal friction of fluids expressed as dyne-seconds/cm² called poise unit. ▶stoke, ▶dyne

Visfatin: A cytokine secreted by adipocytes that mimics the effects of insulin. ▶adipocyte, ▶insulin; Fukuhara A et al 2005 Science 307:426; this paper has been retracted. (Science 318: 565 [2007]).

Visible Mutation: Can be identified by the phenotype seen.

Vision: ▶rhodopsin

Vista: A visualization tool for alignment; also a computer program.

Vital Genes: ▶lethal mutation

Vital Stain: Colors living cells without serious damage to viability.

Vital Statistics: Pertains to birth, marriage and death registrations. Such information may assist in constructing human pedigrees and provide important facts about family histories, congenital and hereditary disease, longevity, etc.

Vitalism: A theory of the nineteenth century and earlier, which postulates that living beings are controlled not only by physical and chemical mechanisms, but life is also associated with a transcendental vital force. However, there still remain phenomena like the development of an embryo or regeneration from single cells that cannot be fully explained in physico-chemical terms although vitalism is no longer a viable idea since Friedrich Wöhler synthesized urea in 1828 from inorganic ingredients. (See Hein H 1972 J Hist Biol 5:159).

Vitamin A: Also known as retinol, it is synthesized from carotenoids. Its deficiency results in visual and skin anomalies (see Fig. V22). However, excessive amounts may be harmful. With the aid of three transformation vectors the β -carotene pathway has been introduced into the carotenoid-free rice endosperm enabling the production of provitamin A and correcting the deficiency in the diet. ▶retinol, ▶retinal

Figure V22. Vitamin A (all trans retinol)

Vitamin B₁: ▶thiamin (see Fig. V23)

Figure V23. Vitamin B₁

Vitamin B₂: ▶riboflavin, ▶riboflavin retention deficiency

Vitamin B₆: ▶pyridoxine

Vitamin B Complex: Includes thiamin, riboflavin, nicotinic acid (amide), pantothenic acid, pyridoxin and vitamin B₁₂.

Vitamin B₁₂ Defects: Vitamin B₁₂ or its coenzyme form has a MW of about 1,355. It is composed of a core ring with Cobalt (Co³⁺) at its center and to it, through isopropanol, a dimethyl benzimidazole ribonucleotide is joined; it also contains a 5'-deoxyadenosine. It is usually isolated as a cyanocobalamin because during the process of purification a cyano group may be attached to the cobalt at the place where the 5'-deoxyadenosyl group is positioned in the coenzyme. B₁₂ is not synthesized in plants and animals

Figure V24. Vitamin B₁₂

and is not usually present in the diet. Intestinal microorganisms produce it from the meat consumed and it is absorbed when the so-called “intrinsic factor,” a glycoprotein, is available in satisfactory amounts. If the intake is less than 3 µg/day, pernicious anemia develops in humans (see Fig. V24). Autosomal recessive mutation may prevent the release of the lysosomally stored vitamin and B₁₂ deficiency may result. Cysteinurias is often called cobalamin F (cbl F) disease. In methylmalonicacidemia combined with homocystinuria, methylmalonyl-CoA mutase and homocysteine methyl-tetrahydrofolate methyltransferase (cbl C) deficiencies are involved. ►methylmalonicaciduria, ►cysteinuria, ►amino acid metabolism, ►cobalamin; Banerjee R, Ragsdale SW 2003 *Annu Rev Biochem* 72:209.

Vitamin C: ►ascorbic acid, formula given here (see Fig. V25)

Figure V25. Vitamin C

Vitamin D: An antirachitic, fat soluble vitamin, whose deficiency leads to rickets and defects in bone development and maintenance. Vitamin D² (ergocalciferol) (see Fig. V26) is formed upon irradiation of ergosterol and vitamin D³ (cholecalciferol) from 7-dehydro-cholesterol. Children need about 20 µg/day in their diet. Autosomal recessive human defects in vitamin D receptors (12q12-q14) do not respond favorably to vitamin D fortified diet. Several cancer cells are inhibited by vitamin D³ and it may induce apoptosis. The use of a sunscreen may reduce the amount of vitamin D below a desirable level. ►Williams syndrome, ►VDR, ►hormone-response

Figure V26. Ergocalciferol

elements; McGuire TF et al 2001 *J Biol Chem* 276:26365; formula.

Vitamin E (tocopherols): Vitamin E is an antioxidant (in several different forms) normally present in satisfactory amounts in a balanced diet (see Fig. V27). Transgenic plants expressing homogentisic acid geranylgeranyl transferase display increased amounts of vitamin E and antioxidant ability (Cahoon EB et al 2003 *Nature Biotechnol* 21:1082). In an autosomal recessive condition vitamin E malabsorption has been observed, causing intestinal and nervous anomalies and accumulation of cholesterol. The severe symptoms could be alleviated by 400–1,200 international units (IU) of vitamin E. It appears that the affected individuals lack an α-tocopherol binding protein, required to build it into very low-density lipoproteins. In a transgenic mouse model vitamin E reduced chromosomal damage and hepatic tumors. The familial vitamin E deficiency is under autosomal recessive control in humans. Doses of 400 IU may be very harmful. ►tocopherols, ►VLDL, ►atherosclerosis; Azzi A et al 2002 *FEBS Lett* 519:8.

Figure V27. Tocopherol

Vitamin K (phylloquinone): A plant lipid cofactor of blood coagulation (vitamin K₁) and a related substance, menaquinone (vitamin K₂) is synthesized by intestinal bacteria of animals; the synthetic menadione (vitamin K₃) also has some vitamin K activity. The name K was derived from the Danish word koagulation. ►vitamin K-dependent blood clotting factors

Vitamin K-Dependent Blood Clotting Factors: Some autosomal recessive bleeding diseases respond favorably to the administration of vitamin K (see Fig. V28). It is required for post-translational modification of at least six proteins involving the conversion of the NH₂-end of glutamic acid into γ-carboxyglutamic acid. Deficiency of this process may occur as a consequence of treatment by coumarin drugs—such as warfarin—used as anticoagulants. A vitamin K-dependent blood coagulation factor is encoded at 2p12 and its mutation is caused by vitamin K-dependent carboxylase (GGCX) in the microsomes

of the liver and includes bleeding disease. Similarly, vitamin K 2,3-epoxide reductase (VKOR) mutations (16p12-q21) in a transmembrane protein of the endoplasmic reticulum lead to familial bleeding. ►prothrombin deficiency, ►resistance to coumarin-like drugs, ►antihemophilic factors, ►warfarin, ►γ-glutamyl carboxylase, vitamin K-dependent blood clotting factors; Li T et al 2004 Nature [Lond] 427:541.

Figure V28. Vitamin K

Vitamins: These are dietary supplements, without measurable caloric value. They serve the role of coenzymes. Widespread dietary supplements can cause selective accumulation of vitamin deficient genotypes in human populations (Lucock M, Yates Z 2005 Nature Rev Genet 6:235).

Vitelline Layer: A yolk (heavier) layer around the eggs.
In mammals it is (a thinner) zona pellucida. ►egg

Vitellogenin: Refers to yolk protein. In honeybees the amount of yolk protein is proportional to longevity because it protects from oxidative stress. ► **longevity**, ► **oxidative stress**; Seehuus A-C et al 2006 Proc Natl Acad Sci USA 103:962.

Vitiligo: Dominant (1p31.3-p32.2) halo skin spots (may be identical on opposite sides of the body) present after birth that may spread or regress. Apparently, loci in several autosomes are also involved in susceptibility. It is an autoimmune disease with an incidence of ~1%. ▶[piebaldism](#), ▶[nevus](#), ▶[skin diseases](#); Alkhatteeb A et al 2002 Hum Mol Genet 11:661; Fain PR et al 2003 Am J Hum Genet 72:1560.

Vitrification: A procedure of protecting sensitive biological material (enzymes, seeds) from deterioration by coating with sugar mixtures (e.g., sucrose and raffinose) which, however, readily dissolve when needed. Vitrification literally means the formation of a glass-like structure. Human oocytes can be preserved in an appropriate vitrification medium and frozen in liquid nitrogen. ►[cryopreservation](#); Yokota Y et al 2001 Steril Fertil 75:1027.

Vitronectin (S protein): A fluid phase protein in the cell binding the C5b-9 complement component which

prevents its attachment to the membrane and thus interferes with lytic activity. ► [complement](#); Tomasini BR, Mosher DF 1991 *Progr Hemost Thromb* 10:269; Seger D et al 2001 *J Biol Chem* 276:16998.

Vivipary: Refers to giving birth to live offspring. In plants the seed germinates before shedding from the fruits. This phenomenon is genetically controlled through abscisic acid metabolism. ► [ABA](#); Paek NC et al 1998 Mol Cell 8(3):336; Jones HD et al 2000 Plant J 21:133.

V(J)D Recombinase: Assembles immunoglobulins and T cell receptors. The activity of this enzyme is facilitated by histone acetylation. ▶immunoglobulins, ▶T cell receptors, ▶antibody gene switching, ▶RSS, ▶accessibility, ▶SCID, ▶ligase, ▶RAG, ▶histone acetyltransferase; Fugmann SD et al 2000 Annu Rev Immunol 18:945; Gellert M 2002 Annu Rev Biochem 71:101; Jung D, Alt FW 2004 Cell 116:299.

VLDL (very low density lipoprotein): This is the 55 nm precursor of LDL and triglycerides. Its core contains cholesteryl ester. In muscle capillaries and adipose tissues the VLDL-triglycerides are removed and exchanges take place with other lipoproteins resulting in the loss of proteins except apolipoprotein B-100 and a smaller (22 nm) particle size. It is now called LDL (low-density lipoprotein). The VLDLR receptor gene (9p24) is very similar to the LDLR but it contains an additional exon. ►low-density lipoproteins, ►familial hypercholesterolemia, ►sitosterolemia, ►sterol, ►Alzheimer's disease, ►hypertension, ►apolipoproteins; Merkel M et al 2001 Proc Natl Acad Sci USA 98:13294.

VLP: A virus-like particle, such as some transposable elements (retroposons). ▶Ty, ▶retroposons

V_{\max} : The maximal level of enzyme activity (maximal velocity reaction).

v-mil: ►MIL, ►MYC

vMIP: ►herpes virus, ►chemokines

VNC: Refers to viable but non-cultivable microbial cells. They may be transgenic (genetically modified) and they may be protected by nucleic acids.

VNO: ► vomeronasal organ, ► olfactogenetics

VNTR (variable number tandem repeats): Loci are used in forensic DNA fingerprinting. These repeats may display hundreds of alleles per single locus and are extremely polymorphic in restriction fragments. They are useful as physical markers for mapping. Also, because matching patterns occur by a chance of 10^{-7} to 10^{-8} only, they are well suited for criminal, personal

and legal identification on the basis of minute amounts of DNA extracted from drops of body fluids, blood or semen. VNTR can also be used for taxonomic and evolutionary studies of animals and plants. ▶DNA fingerprinting, ▶diabetes mellitus, ▶MVR, ▶MLVA, ▶trinucleotide repeats, ▶SSM; Le Stunff C et al 2001 Nature Genet 29:96.

Vogt-Spielmeyer Disease: This is also known as Batten disease. ▶ceroid lipofuscinosis

Volatility: Refers to the proportion of point mutations that encodes a different amino acid. The arginine codon CGA has eight potential ancestor codons, i.e., non-stop codons that differ from CGA by one point mutation. Four of the potential ancestor codons of CGA encode another amino acid. Thus, the volatility is 4/8. If the selection pressure for a particular protein is high, the demand for amino acid replacement increases. ▶selection pressure; Plotkin JB et al 2004 Nature [Lond] 428:942.

Vole: *Microtus agrestis*, 2n = 50; *Microtus arvalis*, 2n = 46; *Microtus montanus*, 2n = 24.

Volicitin: ▶biological control

Volt (V): The unit of electric potential. In case the resistance is 1 Ω (Ohm = 1 V/A = 1 m² kg sec⁻³ A⁻²) and the electric current is 1 ampere, the voltage is 1. ▶ampere, ▶watt

Voltage-Gated Ion Channels: These channels are opened/closed for the transport of ions in response to a change in voltage across cell membranes. ▶ion channels, ▶signal transduction

Volunteer: This plant sprouts from the seed shed on the field and appears after the regular harvest season. The farmer does not plant it.

Vomer nasal Organ (VNO): This is a pair of chemosensory organs at the base of the nasal cavity in the majority of higher animals, except birds and some monkeys and apes (humans). VNO is stimulated by pheromones. MHC class I peptides act as chemosensory signals to the sensory neurons (Leinders-Zufall T et al 2004 Science 306:1033). The signaling through GTP-binding proteins requires 1,4,5-trisphosphate rather than cAMP. In humans, pheromones play either no role or only a subordinate role and the VNOs are apparently non-functional. Apparently, the vision-based signaling-sensory mechanism has replaced the chemical-based system in the social/reproductive activities of hominoids and Old World monkeys (Zhang J, Webb DM 2003 Proc Natl Acad Sci USA 100:8337). In mouse 187 and in rat 102 V1R genes have been identified but in dogs only 8, cows 32 genes and in the marsupial opossum 49 function (Grus WE

et al 2005 Proc Natl Acad Sci USA 102:5767). ▶olfactogenetics, ▶phosphoinositides, ▶cAMP, ▶pheromones, ▶major histocompatibility complex, ▶marsupial; Lane RP et al 2002 Proc Natl Acad Sci USA 99:291.

v-Oncogene: Viral oncogene, homologous to a c-oncogene, but carried by oncogenic viruses, capable of causing cancerous growth. ▶oncogenes, ▶cancer, ▶c-oncogene, ▶retrovirus

Von Gierke Disease: ▶glycogen storage disease

Von Hippel-Lindau Syndrome (VHL): A dominant phenotype (human chromosome 3p26-p25) involving tumorous growth primarily of the blood vessels of the eye (hemangioma) and the brain (hemangioblastoma). The central nervous system, kidneys (phaeochromocytoma) and the pancreas may also become tumorous. The incidence estimates vary between 0.00002 and 0.00003, and the mutation rate appears to be about $2-4 \times 10^{-6}$. The primary cause of the tumor is the inactivation of the VHL tumor suppressor gene. The VHL protein forms ternary complexes with Elongin C and Elongin B and CUL2 (see Fig. V29). This complex marks HIF (hypoxia-inducible factor) for degradation by the proteasome. RBX1 helps to recruit the ubiquitinating proteins. With the assistance of the normal pVHL, the α subunit of HIF is degraded and the level of oxygen increases. This process results in the activation of the CXCR4 chemokine receptor. HIF, with the cooperation of other proteins, e.g., VEGF, promotes the formation of blood vessels that are required for cancerous growth. When pVHL protein formation is reduced or prevented, HIF remains active and creates conditions for angiogenesis and cancerous growth. It is believed that VHL is a negative regulator of VEGF by association with complexes (SCF) which target proteins for degradation. The VHL gene falls in the same area as the RCC gene. The VHL inactivation seems to affect TGF-α and that may stimulate the renal carcinogenic path. ▶ELONGIN, ▶VEGF, ▶CXCR,

Figure V29. HIF pathway in VHL

►eye diseases, ►kidney diseases, ►phaeochromocytoma, ►polycythemia, ►mutation rate, ►renal cell carcinoma, ►hypernephroma, ►RCC, ►SCF, ►SKP, ►cullin, ►angiogenesis, ►wound healing, ►proteasome, ►elongin, ►Rbx1, ►ubiquitin, ►HIF, ►hypoxia; Iwai K et al 1999 Proc Natl Acad Sci USA 96:12436; de Paulsen N et al 2001 Proc Natl Acad Sci USA 98:1387; Ivan M et al 2001 Science 292:464; Friedrich CA 2001 Hum Mol Genet 10:763.

Von Neumann–Morgenstern Gamble: Seriously or terminally ill patients may chose an experimental drug or treatment that may improve the quality of life but may further aggravate the illness and even shorten life.

Von Recklinghausen Disease (NF1): A dominant, human chromosome 17q11.2 neurofibromatosis, a skin tumor with characteristic café-au-lait spots. Some other features include are pseudoarthritis, glioma, mental retardation, hypertension, hypoglycemia, etc. The mutation rate is $\sim 10^{-4}$. The basic defect appears to be in a cytoplasmic GAP protein. ►neurofibromatosis, ►GAP, ►elephant man, ►café-au-lait spot

Von Willebrand's Disease (VWD): A complex, hereditary bleeding condition due to a deficiency of a large antihemophilic cysteine-rich glycoprotein (2813-amino acids) in the blood plasma, platelets and subendothelial connective tissue. It is different from hemophilias inasmuch as the bleeding from the gastrointestinal, urinary system and the uterus is prolonged. Several forms of this disease have been identified on the basis of which component of the large gene is affected. The type III form is characterized by very severe symptoms and is the least common type of VWD. The most common type VWD protein has a binding domain to antihemophilia factor VIII and its defect appears as a relatively rare recessive. There is also an X-linked form. The bleeding can be readily stopped upon supplying normal blood to the patients. The most common dominant gene which leads to a reduction of this glycoprotein has been assigned to human chromosome 12pter-p12.3. In its ~ 180 kb it contains 52 exons. Exon 28 is the largest encoding domains A1 and A2. Domains D1-D2-D'-D3-A1-A2-A3-D4-B1-B2-B3-C-1-C2-CK are distinguished. Its highly homologous pseudogene is located in 22q11.2. At least 22 human genes carry homologies to the A domain of chromosome-12 gene. The frequency of heterozygotes has been estimated to vary from 1.4 to 5%, and thus VWD appears quite frequent although some other estimates are much lower. Recurrence risk for the dominant form, if one of the parents is affected, is about 50%. Both heterozygotes and homozygotes may express VWD. Percutaneous

umbilical blood sampling (PUBS) may permit prenatal diagnosis. ►hemophilias, ►antihemophilic factors, ►Glanzmann's disease, ►hemostasis, ►prenatal diagnosis, ►epiphyseal dysplasia; Sadler JE 2002 Science 297:1128; Manucci PM 2004 New England J Med 351:683.

Von Willebrand–Jürgen's Syndrome: ►thrombopathic purpura

VP: Refers to viral proteins such as the VP1, VP2 and VP3 of Simian virus 40. ►SV40

VP16 (α -transinducing factor, α -TIF): Refers to a herpes simplex virus transcription activation domain that can boost the expression of other genes by a factor of 10^5 . The normally minimal activation is due a peptide module of VP16 called ATF14. A small synthetic molecule, less than 1/5 of ATF14, is almost as efficient and more resistant to proteolytic degradation (Minter RA et al 2004 J Am Chem Soc 126:10504). ►transactivator; Hirst M et al 2001 Proc Natl Acad Sci USA 98:8726.

Vpg: A genome-linked (polio) viral protein (22 amino acids) attaches to the 5' end of RNA viruses and acts as a primer in the replication of the nucleic acid. ►primer

VRE (ventral response element): This is involved in the regulation of ventral development by preventing switching on an activator that operates dorsal development.

vRNA: ►vault

Vrolik Disease: ►osteogenesis imperfecta Type II

VSG: Refers to variable surface glycoprotein. ►Trypanosoma, ►Borrelia, ►telomere switching

VSP (very short patch repair): A prokaryotic repair involving T-G mismatches by restoring the original base pairs. (See Lieb M et al 2001 J Bacteriol 183:6487).

VSV: ►CO₂ sensitivity

V-type ATPases: These are responsible for the acidification of cellular organelles (vacuoles, lysosomes, Golgi complex) by the maintenance of the vacuolar-type ATPase—proton pump in plant and animal cells. ►Golgi complex, ►lysosomes, ►ATPase; Gruber G et al 2001 J Exp Biol 204:2597.

V-type Position Effect: A variegated expression of genes transposed into the vicinity of heterochromatin. This phenomenon is common in *Drosophila* but only a few cases have been observed in plants. One of the most common causes of variegation is the movement of insertion or transposable elements or sorting out of plastid-DNA encoded mutations. ►position effect,

►heterochromatin, ►variegation, ►chloroplast genetics, ►transposable elements

Vulva: This is the outer region of the external female genital organ, the vaginal orifice and organs associated with it.

Vulvovaginitis: An autosomal dominant allergy to semen resulting in vaginal inflammation lasting from a couple to several hours after coitus. The most common cause is, however, infection or candidiasis. ►candidiasis; Eschenbach DA 2004 New England J Med 351:851.

Historical vignettes

RC Punnett (Heredity 4:9) gives the following account: “I was asked why it was that, if brown eye were dominant to blue, the population was not becoming increasingly brown eyed: yet there was no reason for supposing such to be the case. I could only answer that the heterozygous browns also contributed their quota of blues and that somehow this led to equilibrium. On my return to Cambridge I at once sought out GH Hardy with whom I was then very friendly. For we had acted as joint secretaries to the Committee for the retention of Greek in the Previous Examination and we used to play cricket together. Knowing that Hardy had not the slightest interest in genetics, I put my problem to him as a mathematical one. He replied that it was quite simple and soon handed to me the now well-known formula $p^2 + 2pq + q^2$ (where p , $2q$ and r the proportions of AA, Aa, and aa individuals in the population varying for the A-a difference). Naturally pleased at getting so neat and prompt an answer I promised him that it should be known as ‘Hardy’s Law’— a promise fulfilled in the next edition of my Mendelism. Certain it is...that ‘Hardy’s Law’ owed its genesis to a mutual interest in cricket.”

Vannevar Bush, Director of the US Office of Scientific Research and Development, 1938 on science policy: “Scientific progress on a broad front results from the free play of free intellects, working on subjects of their own choice, in the manner dictated by their curiosity for exploration of the unknown.”

W

w: A symbol of map distance. ▶ θ , ▶map distance, ▶cM, ▶recombination, ▶mapping function

W Chromosome: This corresponds to the Y chromosome in heterogametic females, WZ in birds and butterflies. ▶chromosomal sex determination

w Locus: The first mutation discovered in *Drosophila* by Morgan is involved in the control, production and distribution of brown (ommochrome) and red (pteridine) pigments of the eyes and ocelli and some other anatomical structures. The gene (at 1–1.5) apparently encodes an ATP-binding membrane transport protein for the precursors of the pigments. More than 200 alleles have been identified within a 0.03 centimorgan region, which has been mapped by intragenic recombination into 7 domains. The wild type allele is incompletely dominant over many mutant alleles. The alleles do not show partial complementation with the exception of the w^{sp} (white spotted) allele that displays allelic complementation with the majority of other alleles in the presence of the z^a (*zeste*). The latter is a regulatory gene at 1–1.0 location and *zeste* encodes a specific protein binding to the promoters of *w*, *Ultrabithorax* (*Ubx*) and *decapentaplegic* (*dpp*). ▶map unit, ▶recombination, ▶morphogenesis in *Drosophila*, ▶eye color, ▶Tangier disease

W Mutagenesis: A tendency of increased mutation after Weigle reactivation. ▶Weigle; Yatagai F et al 1983 Adv Space Res 3(8):65.

W Point: A stage just before the S phase when animal cells still have serum growth factor requirement to enter the S phase. ▶cell cycle

W Reactivation: This is the same as Weigle reactivation.

Waardenburg Syndrome: Autosomal dominant forms may be distinguished on the basis of displacement (type I) and without displacement (type II) of the eyelids. Variegation in the color of the iris, white forelock, eyebrows and eyelashes, syndactyly, heart problems, hearing defects may occur as autosomal recessive anomaly. Dominant mutations in the SOX10 gene may affect the neural crest-derived cell lineages. The Waardenburg syndrome type 2 gene (MITF [microphthalmia-associated transcription factor]) converts fibroblasts into melanocyte-like cells by transactivation of a tyrosinase gene. If MITF is inactive hypopigmentation occurs. Mutation in the PAX3 transcription factor is responsible for hearing and pigmentation defects of type 1 form caused by failure of

transactivation of MITF. Human chromosomal locations are type I 2q35, type IIA 3p14.1-p12.3 and type IIB 1p21-p13.3. The type III form also called Klein-Waardenburg syndrome is at 2q35 location. The syndrome may be haplo-insufficient. The merle phenotypes observed in several breeds of dogs are characterized by hypopigmentation and by hearing and eye defects is caused by insertion of SINE elements into the *SILV* (silver) gene, responsible for pigmentation. The merle phenotype is similar to the Waardenburg type II anomaly (Clark LA et al 2006 Proc Natl Acad Sci USA 103:1376). ▶PAX, ▶DiGeorge syndrome, ▶eye defects, ▶eye color, ▶polydactyly, ▶microphthalmos, ▶haplo-insufficient, ▶Shah-Waardenburg syndrome, ▶dog; Sánchez-Martín M et al 2002 Hum Mol Genet 11:3231.

Waardenburg-Shah Syndrome: ▶Shah-Waardenburg syndrome

WAF: ▶p21

WAGR: ▶Wilms tumor

Wahlund's Principle: When two populations, each with different allelic frequencies and both in Hardy-Weinberg equilibrium, are mixed by migration, there is an overall decrease in heterozygotes: $\bar{H} = 2\bar{p}\bar{q}[1 - (\sigma^2/\bar{p}\bar{q})]$. The decrease in overall heterozygosity indicates the degree of heterogeneity between the two populations and $(\sigma^2/\bar{p}\bar{q})$ is the Wahlund's variance of gene frequencies. ▶allelic frequencies, ▶migration; Yasuda N 1968 Am J Hum Genet 20:1.

Wald-Wolfowitz Test: Used for comparison of two unmatched, supposedly continuous distributions and the null hypothesis is that the two samples are distributed identically. ▶null hypothesis, ▶logistic regression; Hays WL, Winkler RL 1970 Statistics: Probability, Inference, and Decision. Holt, Reinhart and Winston, New York.

Waldemar of Prussia: A hemophiliac great-grandson of Queen Victoria. ▶hemophilia A, ▶Queen Victoria

Waldenström Syndrome: ▶macroglobulinemia

Walker Boxes (P-loops): These are nucleotide triphosphate-binding amino acid sequences in several proteins. Box A promotes branch migration in Holliday junctions during recombination mediated by the Ruv B protein. Walker A: GlyXXGlyXGlyLysThr, Walker B: AspGluXAsp. The Lys residue binds the γ -phosphate of nucleotides directly. ▶branch migration, ▶Holliday junction, ▶RuvABC; Walker JE et al 1982 EMBO J 1:945; Hishida T et al 2001 J Biol Chem 274:25335.

Walker-Wagner Syndrome: An autosomal recessive hydrocephalus (accumulation of fluid in the enlarged

head) generally associated with retinal detachment, congenital muscular dystrophy and lissencephaly. ▶[Miller-Dieker syndrome](#), ▶[hydrocephalus](#), ▶[prenatal diagnosis](#), ▶[head/face/brain defects](#), ▶[lissencephaly](#)

Walker-Warburg Syndrome (HARD, 9q31): Refers to autosomal recessive hydrocephalus agyria and retinal dysplasia that was originally described as lissencephaly. ▶[Miller-Dieker syndrome](#); Beltrán-Valero de Barnabé D et al 2002 Am J Hum Genet 71:1033.

Walking: ▶[chromosome walking](#)

Walking of Transcriptase: Describes transient halting of the movement of the RNA polymerase ternary complex (polymerase, DNA, transcript) by sequentially providing subsets of the four ribonucleotides. ▶[transcript elongation](#)

Wallaby: *Wallabia bicolor*, 2n = 11 in males and 10 in females; *Wallabia eugenii* 2n = 16.

Wallaby: A non-viral retrotransposable element named after the jumping small Australian kangaroo. ▶[retroposon](#)

Walnut (*Juglans* spp): Occurs in both wild and cultivated forms; 2n = 2x = 32.

Walnut Comb: In poultry, it is determined by the genetic constitution *RrPp*, and as a result of epistasis, occurs in 9/16 frequencies in F₂ after brother-sister mating of the same double heterozygotes (see Fig. W1). The other phenotypes in the segregating F₂ are rose *Rr/RR, pp* (3), pea *rr, PP/Pp* (3), and single *pp, rr* (1).

Walrus: *Odobenus rosmarus*, 2n = 32.

Waltzing Mouse: A chromosomal deletion causing involuntary movements.

Wanda: ▶[fish orthologous genes](#)

Wandering Spots: An older method of sequencing short oligonucleotides. (Le Gall O et al 1988 J Gen Virol 69:423).

Warburg Effect: ▶[glycolysis](#)

Warburg Micro Syndrome (2q21.3): A condition characterized by autosomal recessive microcephaly, micropupil, congenital cataract, mental and physical retardation, underdeveloped genitalia, facial

hairiness, hypoplasia of the corpus callosum and other anomalies. The molecular defect appears to be in the RAB3 GTPase activating protein. ▶[corpus callosum](#), ▶[RAB](#), ▶[Griscelli syndrome](#); Aligianis IA et al 20005 Nature Genet 37:221.

Ward-Romano Syndrome (WRS, 11p15.5): An autosomal dominant or recessive LQT disease involving anomalous heart muscle fibrillations, fainting (syncope) and possibly sudden death. It is the same as long QT syndromes. ▶[LQT](#), ▶[electrocardiography](#), ▶[ion channels](#), ▶[HERG](#), ▶[Jarvell and Lange-Nielson syndrome](#), ▶[long QT syndrome](#), ▶[Andersen syndrome](#)

Warfarin (C₁₉H₁₆O₄, named after Wisconsin Alumni Research Foundation): This is a slightly bitter, water and alcohol soluble compound. It depresses the formation of prothrombin, necessary for blood clotting, and may cause fragility of the capillary veins leading to hemorrhages. It is used in certain surgeries and treatment of diseases that block arteries by blood clots. It is also a rodent poison. A single ingestion may not necessarily be very hazardous to humans but rats or mice consuming it repeatedly in baits suffer internal bleeding and die. The antidote of warfarin is vitamin K. Warfarin inhibits vitamin K epoxide reductase. Mutations in rodents may make them resistant to warfarin. ▶[anticoagulation factors](#), ▶[prothrombin deficiency](#), ▶[coumarin-like drug resistance](#), ▶[vitamin K-dependent clotting factors](#), ▶[chondrodysplasia](#); Van Aken H et al 2001 Clin Appl Thromb Hemost 7:195; Loebstein R et al 2001 Clin Pharmacol Ther 70(2):159.

Wasp: Wiskott-Aldrich syndrome proteins that regulate the assembly of actin monomers into filaments and regulate the cytoskeletal organization and motility of cells. WASF1 encoded at 6q21-q22 and WASF3 at 13q13 are effectors for the signal transmission from tyrosine kinase receptors to the cytoskeleton. The function of WASF2 (1p36.11-p34.3) is also similar. The latter has a pseudogene at Xp11.22. ▶[Wiskott-Aldrich syndrome](#), ▶[actin](#), ▶[cytoskeleton](#); Ward ME et al 2004 Proc Natl Acad Sci USA 101:970.

Wasp: *Habrobracon* spp. 2n = 20 for female, 2n = 10 for male. The males hatch from unfertilized eggs and are haploid. The females come from fertilized eggs and are diploid. They are heterozygous for any of the

Figure W1. From left to right: Walnut, Rose, Pea, Single comb

nine sex factors. As a result of inbreeding, sex factor homozygotes occasionally arise that are sterile “biparental males” (see Fig. W2). Gynandromorphs occur in wasps but these are different from those in *Drosophila* because the haploid sectors are not necessarily male sectors as expected from the loss of one set of chromosomes. Although in insects circulating sex hormones do not seem to exist, some type of diffusible substance affects the chromosomally male sectors. Exceptional gynandromorphs may arise by fertilization of binucleate eggs. Gynandromorphic tendency is genetically determined. ►social insects, ►honey bee; Page RE et al 2002 Genetics 160:375; Cowan DP, Stahlhut JK 2004 Proc Natl Acad Sci USA 101:10374.

Figure W2. Wasp (Right-side wings and legs removed)

Watercress (*Rorippa nasturtium-aquaticum*): This is a northern European vegetable with $x = 16$ but the species may be diploid, sterile triploid or tetraploid.

Watermelon (*Citrullus vulgaris*): An annual fruit, $2n = 22$. Triploids are grown commercially and crossing tetraploid plants with diploids produces the seeds. The fruits of the triploid plants are practically seedless and are therefore easier to eat (see Fig. W3). According to some reports, triploids have a higher sugar content than either of the parental forms.

Figure W3. Watermelon. (Diagram of watermelons modified after Eigsti OJ, Dustin P Jr 1955 Colchicine, Iowa State College Press, Ames, Iowa)

Watson and Crick Model: This has been described by Watson JD, Crick FHC in 1953 (Nature [Lond] 171:964) and it became the world’s most famous biological model ever conceived. (See Fig. W4 of the model, and Fig. W6 for historical documents: <http://osulibrary.orst.edu/specialcollections/coll/pauling/dna/>).

It is interesting to note in the first DNA models of Watson and Crick (1953) only two hydrogen bonds have been shown between G and C. The third hydrogen bond between G and C was first mentioned in a paper by Pauling and Corey in 1956 (Waine-Hobson S 2006 Nature [Lond] 439:539). The genome of the first human being that was entirely sequenced in 2007 belongs to James Watson (Project Jim). He agreed that his DNA sequence should be added to public databases but requested that his *ApoE* gene status – which is indicative of a risk for Alzheimer’s disease – be blanked out. It is likely that other disease susceptibility gene sequences will not be made public either (Marshall E 2007 Science 315:1780).

Watt (W): The product of volts and amperes in the case of direct current. $1\text{ W} = 1\text{ joule/sec} = 0.293\text{ calories/sec} = 1/735\text{ HP (horse power)}$. In other words, 1 W power is generated by the electric potential between two points of 1 volt and 1 ampere current. ►volt, ►ampere

Wax Coat: ►eceriferum

WCPP (whole chromosome painting probe): Contains a combination of many probes, specific for a single chromosome and thus may label with color its entire length. The multicolor labeling probes may permit the differentiation of all chromosomes in a single karyotype. ►chromosome painting, ►USP, ►FISH, ►GISH

WD-40: Refers to a repeat (N) motif of tryptophan (W) - aspartic acid (D) in several eukaryotic regulatory proteins (absent in prokaryotes) (see Figs. W5); WD repeats are involved in signal transduction, RNA processing, developmental regulation, cell cycle, vesicular traffic, etc. ►signal transduction; Neer EJ et al 1994 Nature [Lond] 371:2987; Smith TF et al 1999 Trends Biochem Sci 24:181.

W-DNA: Refers to a left-handed zig-zag duplex with the same directions as B-DNA but other characteristics match those of the Z-DNA. ►DNA types

Weasel: *Mustela erminea*, $2n = 44$; *Mustela frenata*, $2n = 44$.

WEB Service: This is a standard system of communication of machines in a network.

WEBB (WB): A very rare blood group involving an altered glycosylation of glycophorin. ►glycophorin,

Figure W4. The double-stranded DNA molecule is joined through 2 and 3 hydrogen bonds between the A = T and G = C nucleotides, respectively. The staircase-like ribbons represent the sugar-phosphate backbone of the double helix. During replication the old plectonemic strands unwind and each old separated strand serves as a template for the formation of the new molecules that are composed from one old and one new single strand (►DNA replication, ►replication fork). This is, therefore, known as the semi-conservative mode of replication. The model is consistent with most genetic phenomena (mutation, recombination, gene expression, etc.). Since the model was originally proposed, the details of the mechanisms of the DNA transactions have been worked out in greater detail but basically none of the essential features had to be revised. This model served as a basis for the *central dogma of genetics* indicating that the flow of information is from the DNA to the RNA and to protein. During the 1960s it was discovered that through reverse transcriptase information can be directed by reverse transcription from the RNA to the DNA but not from protein to the RNA and the DNA. The discovery of prions makes the role of proteins in heredity somewhat ambiguous. All other proposals concerning hereditary molecules (besides the DNA and the RNA) have now faded into oblivion

Figure W5. WD-40

Wegener Granulomatosis: An autosomal dominant condition characterized by the presence of a ~29 kDa serine protease antigen, identical to myeloblastin. It is a very serious ailment primarily affecting the upper and lower airways and kidneys. ▶myeloblast, ▶Goodpasture syndrome

Weibel-Palade Bodies: These are $0.1\text{--}0.2\text{ }\mu\text{m} \times 4\text{ }\mu\text{m}$ membrane-enclosed bodies found around the platelets or in the endothelium of all animals. They store in their $150\text{--}200\text{ }\text{\AA}$ tubules the von Willebrand glycoprotein. ▶von Willebrand disease; Denis CV et al 2002 Proc Natl Acad Sci USA 98:4072.

Weighted Mean: Refers to the calculated mean multiplied by the pertinent frequency, e.g., in a population the mean value of the homo- and heterozygous dominants (*AA* and *Aa*) is 250 and that of the

homozygous recessives (*aa*) is 200, and the respective frequencies are 0.8 and 0.2, then the weighted mean of the population is $(250 \times 0.8) + (200 \times 0.2) = 240$.

▶mean

Weigle Mutagenesis: Denotes an increase in mutation of phage by mutagenic treatment of the host. (See Weigle JJ 1953 Proc Natl Acad Sci USA 39:628; Bhattacharyya SC et al 1991 Can J Microbiol 37:265).

Weigle Reactivation: An increase in phage survival when mixed with host cells exposed to low doses of UV light. ▶DNA repair, ▶marker rescue, ▶multiplicity reactivation; Calsou P, Salles B 1991 Mol Gen Genet 226:113.

Weismannism: Inheritance takes place by the transmission of the genetic determinants through the germ line (Keimbahn) and environmentally-induced phenotypic

variations are not inherited. ► [germ line](#); Weismann A 1985 Die Continuität des Keimplasmas als Grundlage einer Theorie der Vererbung. Fischer, Jena, Germany.

Weissenbacher-Zweymuller Syndrome (WZS, 6p21.3): A condition characterized by neonatal small jaws (micrognathia), hip and/or shoulder bone defects (rhizomelic chondrodysplasia), general underdevelopment of bones that may improve in later years optic nerve defects, myopia and deafness. Some of the symptoms resemble those of the Stickler syndrome. The basic defect is in the collagen gene COL11A2. ► [collagen](#), ► [Stickler syndrome](#)

Welander Distal Myopathy (WDM, 2p13): A dominant late-onset muscular dystrophy. ► [muscular dystrophy](#), ► [Miyoshi myopathy](#)

Werdnig-Hoffmann Disease: A recessive (5q12.2-q13) infantile muscular dystrophy primarily affecting the spinal cord muscles. The prevalence is approximately 1×10^{-4} . The gene frequency has been estimated to be around 0.014 and the frequency of heterozygotes about 0.02. It encodes a protein that shows homology to dystrophin. The survival rate varies according to the severity of symptoms. A subunit of transcription factor TFIIF usually suffers deletions. ► [dystrophin](#), ► [muscular dystrophy](#), ► [neuromuscular diseases](#), ► [spinal muscular atrophy](#), ► [transcription factors](#)

Werner Syndrome (WRN): Involves premature aging, hardening of the skin, cataracts, atherosclerosis, diabetes mellitus, etc. The gene expression profile is similar to that seen in normal aging (Kyng KJ et al 2003 Proc Natl Acad Sci USA 100:12259). Cultured cells have higher chromosome breakage and mutability. Neoplasias develop frequently. Ulceration around the ankles and soft tissue calcification are symptoms of this condition, unrelated to aging. It was earlier held that the recessive defect was controlled by human chromosome Xp12-p11.2 but recent linkage information, including complete sequencing on the basis of positional cloning, confirms its location at 8p12. WRN contains four structurally folded domains comprising an exonuclease, a helicase, a winged-helix and a helicase-and-ribonuclease D/C-terminal domain. The protein is required for focus forming activity in DNA replication (FFA). It contains 1,432 amino acids and resembles RecQ type ATP-dependent helicases (homologous to budding yeast *SGS1* and *SRS2* genes). Defects in the helicase (frameshift, nonsense mutation) explain most of the symptoms in terms of a flaw in DNA metabolism. WRN also interacts with DNA polymerase δ . However, the amino end domain of WRN shows 3'→5' exonuclease activity and it may be involved in genetic recombination and/or repair. Forced telomerase activity substantially extends the life span of cultured WRN

cells. The WRN gene may be inactivated by CPG island hypermethylation at its promoter. Since WRN involves DNA repair, inactivation may lead to loss of exonuclease-mediated DNA repair and increased chromosomal instability as well as to apoptosis, induced by a camptothecin analog (irinotecan), a topoisomerase inhibitor. Thus, cancer cells may become more amenable to chemotherapy (Agrelo R et al 2006 Proc Natl Acad Sci USA 103:8822). Normal fibroblasts and U2OS osteosarcoma cells rendered deficient in WRN exhibit reduced phosphorylation of p53 and histone H2AX in response to T-oligo (telomere single-strand overhang) treatment indicating its role in the processing of telomeric DNA and subsequent activation of DNA damage responses (Eller MS et al 2006 Proc Natl Acad Sci USA 103:15073). There is evidence that the genome instability in WS cells depends directly on telomere dysfunction, linking chromosome end maintenance to chromosomal aberrations in this disease (Crabbe L et al 2007 Proc Natl Acad Sci USA 104:2205). ► [aging](#), ► [progeria](#), ► [helicase](#), ► [exonuclease](#), ► [FFA](#), ► [Bloom syndrome](#), ► [co-suppression](#), ► [RNAi](#), ► [atherosclerosis](#), ► [telomeres](#), ► [translesion](#); Kamath-Loeb AS et al 2000 Proc Natl Acad Sci USA 97:4603; Shen J-C, Loeb LA 2000 Trends Genet 16:213; Kawabe Y et al 2001 J Biol Chem 276:20364; Kipling D et al 2004 Science 305:1426.

Wernicke-Korsakoff Syndrome: A chromosome 3p14.3 recessive disorder involving transketolase deficiency caused by the lowered ability of the enzyme to bind thiamin pyrophosphate. Another transketolase deficiency has been traced to Xq28. This dysfunction of energy metabolism leads to neuropsychiatric anomalies, especially in alcoholics and when the level of thiamin is low in the diet. ► [thiamine pyrophosphate](#)

West Nile Virus (WNV, Flaviviridae): A single-stranded RNA virus. E-glycoprotein is its most important protein, both structurally and for infection (see Fig. W7). Of the two strains, lineage 1 has caused most of the health problems in the US. Outbreaks of the epidemic have been described in Africa, the Mid East and southern Europe. About 29 species of mosquitos transmit the virus to birds and from birds to humans. In North America the human- and bird-biter forms of the *Culex* mosquitos form hybrids and may facilitate the severity of transfer between these species (Fonseca DM et al 2004 Science 303:1535). If infected mosquitos feed in close vicinity of non-infected individuals, the secreted saliva is sufficient for transmission of the virus in an appreciable frequency (5.8%) even when the blood of vertebrates does not contain the virus (non-viremic). This contributes to the rapid spread of the disease (Higgs S et al 2005 Proc Natl Acad Sci USA 102:8871). The symptoms include

fever, headache, gastrointestinal and mental changes (memory loss, depression); rash, cough and other symptoms may also be manifested. The virus appears genetically quite stable. The fatality ranges from 4 to 14% but in older or immune-compromised persons the risks may be more than double. The most effective diagnosis reveals immunoglobulin M (IgM) in the cerebrospinal fluids. RNAi holds promise for effective medication against viral encephalitis at least in mice. However, mosquito control is the key to prevention.

Figure W7. West Nile virus with heavy capsule and two concentric lipid layers surrounding the core with RNA

DNA vaccine coding for the RNA transcript of the related Kunjin flavivirus has protective effects against the West Nile Virus (Hall RA 2003 Proc Natl Acad Sci USA 100:10460). ▶[immunization genetic](#), ▶[viral encephalitis](#); Petersen LR, Marfin AA 2002 Annals Int Med 137:E173; Brinton MA 2002 Annu Rev Microbiol 56:371; <http://westnilemaps.usgs.gov>; <http://www.cdc.gov/ncidod/dvbid/westnile/>.

West Syndrome (ARX, Xp22.13; ISSX, Xp21.3-p22.1): This involves an X-linked central nervous defect, hypsarrhythmia (electroencephalographic anomaly) resulting in infantile spasms and mental retardation. Its incidence is $2-5 \times 10^{-4}$ at birth. The basic defect may be in the serine-threonine kinase 9 region. ▶[epilepsy](#), ▶[mental retardation X-linked](#); Kalscheuer VM et al 2003 Am J Hum Genet 72:1401.

WGRH (whole genome radiation hybrid): Formed when the donor is a diploid cell line for the generation of radiation hybrids. ▶[radiation hybrid](#); Vignaux F et al 1999 Mamm Genome 10:888.

WGA (whole genome association, whole genome assembly, whole genome array). Whole genome association study attempts to identify all the genetic factors involved in the development of a particular disease. The PLINK software tool can handle a very large set of data involving five main domains of function: data management, summary statistics, population stratification, association analysis, and identity-by-descent estimation (Purcell S et al 2007 Am J Hum Genet 81:559). ▶[microarray hybridization](#), ▶[genome annotation](#)

WGS (whole-genome shotgun sequencing): Developed by Craig Venter and associates at Celera Genomics, Rockville, MD, USA. The genome is sheared into a few thousand base pair long pieces and cloned into sequencing vectors. Each fragment end (~500 bp) is covered by the sequencing several times and then assembled into overlapping segments by end-sequences. In this way oriented, contiguous sequences (contigs or scaffolds) are generated. Between the scaffolds a physical gap may remain until the physical map is “finished” and the complete genome is reconstructed with the aid of high-power computers. The scaffolds are also mapped to eukaryotic chromosomes and chromosome arms with the aid of sequence-tagged sites. The heterochromatic regions (mainly around the centromeres and near the telomeres) are unstable when cloned and thus resist sequencing. These regions contain transposons and redundant ribosomal RNA genes with a few interspersed ORFs. For the repeated sequences the WGS method provides less resolution (She X et al 2004 Nature [Lond] 431:927). The function of the sequences is indicated by annotation using Genscan or Genie computer software. ▶[shotgun sequencing](#), ▶[mate pair](#), ▶[sequence-tagged sites](#), ▶[transposon](#), ▶[ribosomal RNA](#), ▶[ORF](#), ▶[annotation](#), ▶[gene ontology](#), ▶[scaffolds in genome sequencing](#), ▶[genome projects](#); Adams MD et al 2000 Science 287:2185; <http://www.ncbi.nlm.nih.gov/projects/WGS/WGSprojectlist.cgi>.

Wheat: ▶[Triticum](#)

Wheat Germ In Vitro Translation: Cell-free wheat germ extracts can be used for the translation of viral, prokaryotic and eukaryotic mRNAs into protein. The supernatant of the extract must be chromatographically purified from inhibitory endogenous amino

acids and pigments before translation. Tritin, one of the endosperm proteins, inactivates the ribosomes and thus reduces the efficiency of the system unless carefully removed. The extract contains tRNA, rRNA and other factors required for protein synthesis. Phosphocreatin and phosphocreatine kinase additions are needed for supplying energy. Spermidine is added to stimulate the translation efficiency and prevent premature termination of the polypeptide chain. Magnesium acetate and potassium acetate, mRNA (to be translated) and amino acids (including one in a radioactively labeled form) are also necessary. Incubation is at 25°C for 1 to 2 hours. In general, the procedure is very similar to the rabbit reticulocyte system. ► [rabbit reticulocyte in vitro translation system](#); Erickson AH, Blobel G 1983 *Methods Enzymol* 96:38.

Whim Syndrome (2q21): Refers to hypogammaglobulinemia, neutropenia, myelokathexis (retention of bone marrow neutrophils) and papilloma virus susceptibility due to mutations in the chemokine receptor CXCR4. ► [gammaglobulin](#), ► [neutropenia](#), ► [neutrophil](#), ► [CXCR](#), ► [papilloma virus](#); Hernandez PA et al 2003 *Nature Genet* 34:70.

Whipple's Disease: An infectious disease caused by *Tropheryma whipplei* bacteria.

White Blood Cell: ► [leukocyte](#)

White Forelock: ► [forelock](#), ► [white](#)

White Leghorn (chicken): Has genes controlling the color of the plumage *CC*, *OO*, *II*; the color is white (see Fig. W8). *C* and *O* both are needed for pigmentation but *I* is an inhibitor of color. ► [White Silkie](#), ► [White Wyandotte](#)

Figure W8. White leghorn rooster

White Matter: ► [gray matter](#)

White Silkie (chickens): They are of the constitution *cc*, *OO*, *ii* and have white feathers because only one of the two dominant genes, *O*, required for pigmentation is present. ► [White Leghorn](#), ► [White Wyandotte](#)

White Wyandotte (chickens): They have the genes *CC*, *oo*, *ii* and are white because only one, *C*, of the two dominant genes is present but not the other, *O*. ► [White Leghorn](#), ► [White Silkie](#)

Whooping Cough: A respiratory disease in humans caused by the pertussis toxin of the bacterium *Bordatella pertussis* (3,816 genes). Species such as *B. paraptus* (4,404 genes) and *B. bronchiseptica* (~5,007 genes) are related pathogenic species for various mammals (Parkhill J et al 2003 *Nature Genet* 35:32). ► [pertussis toxin](#), ► [microfluidics](#)

Whorl: Refers to a circular or spiral arrangement of structures, such as various parts of flowers or the dermal ridges in a human fingerprint. ► [fingerprinting](#), ► [flower differentiation](#)

Wide Cross: Refers to hybridization between plants of different species or genera.

Widow's Peak: An autosomal dominant pointed hairline in humans (see Fig. W9).

Figure W9. Widow's peak

Wilcoxon's Signed-Rank Test: A non-parametric substitute for the t-test for paired samples (see Table W1). The desirable minimal number of paired samples is 10 and it is expected that the population would have a median, be continuous and symmetrical. The differences between the variates are tabulated and ranked; the largest receives the highest rank. In the case of ties, each should be assigned to a shared rank. The smaller group of signed-rank values is then summed as the T value. This T value is compared with figures in a statistical table. If the value obtained is smaller than that in the body of the table under probability and on the line corresponding to the number of pairs tested, then the null hypothesis is rejected and the conclusion is justified that the two samples are different.

Example: Since T being 8.0 according to the first line of Table T1, the difference between the two sets of data is significant at the level of 0.05 probability but not at the 0.01 level.

Table W1. Wilcoxon's Signed-Rank Test

| Pairs | Difference | Signed | Ranks | Probability | | |
|----------------|------------|--------|-------|-------------|------|------|
| | | + | – | <i>n</i> | 0.05 | 0.01 |
| 1 | +6 | 7 | | 10 | 10 | 5 |
| 2 | +5 | 6 | | 11 | 13 | 7 |
| 3 | +10 | 10 | | 12 | 17 | 10 |
| 4 | –3 | | 4 | 14 | 25 | 16 |
| 5 | +4 | 5 | | 16 | 35 | 23 |
| 6 | +7 | 8 | | 18 | 47 | 33 |
| 7 | –2 | | 3 | 20 | 60 | 43 |
| 8 | –1 | | 0.5 | 22 | 75 | 55 |
| 9 | +9 | 9 | | 24 | 91 | 69 |
| 10 | –1 | | 0.5 | 26 | 110 | 84 |
| <i>T</i> = 8.0 | | | | | | |

A more general procedure for determining the probabilities depends on determining the *Z* value either for threshold probabilities or more precisely by using a table of the cumulative normal variates (such as the *Biometrika Tables for Statisticians*, Vol. 1, Pearson ES, Hartley HO, (Eds.), Cambridge University Press, Cambridge). *Z* values larger than 1.960, 2.326 and 3.291 correspond to *P* 0.05, 0.01 and 0.001, respectively. These probabilities rule out the null hypothesis.

$$Z = \frac{\mu - T - 0.5}{\sigma} \text{ and } \mu = \frac{n(n+1)}{4} \text{ and } \sigma = \sqrt{\frac{[2n+1]\mu}{6}}$$

where *n* = the number of paired data. ►non-parametric statistics, ►Mann-Whitney test, ►Student's *t* distribution, ►QTL

Wild Type: The standard genotype (that is most common in wild [feral] populations). ►isoalleles

Wildervanck Syndrome: This appears to be a X-linked dominant deafness, frequently associated with other disorders. Approximately 1% of deaf females is affected by it. It does not occur in males, presumably because it is lethal when homo- or hemizygous. It has been suggested that it is polygenically determined but the mechanism of male exclusion is as yet unknown. ►deafness, ►sex-limited, ►imprinting

Wildfire Disease of Plants: Caused by the toxin (methionine analog) of the bacterium *Pseudomonas tabaci*, and it leads to necrotic spots on the leaves. ►*Pseudomonas*

Williams Factor (Flaujeac factor deficiency): An autosomal recessive mutation in human chromosome

3q26-qter causing deficiency of a high molecular weight kininogen, a precursor of a blood clotting factor. ►kininogen, ►blood clotting pathways, ►antihemophilic factors

Williams Syndrome (Williams-Beuren syndrome, WMS): This autosomal dominant condition involves stenosis (narrowing) of the aorta, arteries and lungs, elfin face (elfins are diminutive mythological creatures), malformation of teeth and stature, mental deficiency and excessive amounts of calcium in the blood (hypercalcemia) and in some tissues. Cognitive abilities are impaired in an unusual fashion. During infancy patients are poor in language skills but their performance is relatively better in numerical intelligence tests. By adulthood the trend is reversed indicating that these abilities are under the control of two different developmental modules. Various types of deletions in different chromosomes (15, 4, 6) have been suspected. Chromosome-specific probes have revealed a ~1.5 Mb deletion of 7q11.23. This region harbors several genes including the GTF21RD1 basic transcription factor and the Williams syndrome transcription factor (WSTF/WCRF/ACF), which bears structural similarity to a 180 kDa chromatin-remodeling factor. The differences in the phenotypes of affected individuals may be due to the dosage effect of the chromosomal segments of this tract. Lower calcium in the diet may alleviate some of the symptoms. Vitamin D2 anomaly is suspected. The function of the Williams factor is unrelated. Recent findings have indicated the involvement of LIMK protein kinases (carrying two LIM domains) that are serine/threonine/tyrosine kinases and regulate

actin in the cytoskeleton. Under normal conditions RAC-GTP activates the LIM kinases that in turn phosphorylate cofilin and inactivate it. Dephosphorylation permits the formation of active cofilin that is associated with actin. The actin—cofilin association is apparently mediated by phosphoinositides (PtdInsP₂). Defects (heterozygosity for a mutation) in LIMK lead to abnormal neuronal connections. Elastin defects characterize the symptoms of the Williams syndrome. ▶supravalvular aortic stenosis, ▶cutis laxa, ▶cardiovascular diseases, ▶dwarfism, ▶vitamin D, ▶Williams factor, ▶LIM domain, ▶face/heart defects, ▶cofilin, ▶actin, ▶phosphoinositides, ▶human intelligence, ▶module, ▶Marfan syndrome, ▶BTK; Peoples R et al 2000 Am J Hum Genet 66:47; MorrisCA, Mervis CB 2000 Annu Rev Genomics Hum Genet 1:461; Sumi T et al 2001 J Biol Chem 276:23092; Urbán Zs et al 2002 Am J Hum Genet 71:30; Bayés M et al 2003 Am J Hum Genet 73:131; Tassabehji M et al 2005 Science 310:1184.

Wilms Tumor (WT): This is usually associated with a deletion in the short arm of human chromosome 11 extending from 11p13 to 11p15.5 (WT1) spanning several genes and is frequently referred to as the WAGR syndrome (Wilms tumor-aniridia-genitourinary anomalies and RAS oncogene-like function). The condition is characterized by symptoms of all or parts of the functions implied by WAGR. Wilms tumor is caused by a mutation in a cancer-suppressor transcription factor and splicing factor with 4 Zn finger domains. Wilms tumor is extremely complex and additional WT genes in chromosomes 16q, and 1p, 4p, 8p, 14p, 17p and q, 18q have also been implicated. The transcript displays alternative splicing. Wilms tumor suppressor gene is expressed only in the maternally transmitted allele. Prevalence is about 10^{-4} during the first five years of age. Recent evidence has revealed a WT gene in the 17q12-q21 region. The WT1 gene also regulates muscle differentiation. The WT1 gene affects the SRY locus in the Y chromosome and that explains the symptoms associated with genitourinary development when it is altered. The different functions are based on isoforms of the protein. ▶aniridia, ▶RAS, ▶deletion, ▶hypertension, ▶kidney diseases, ▶Zinc finger, ▶breast cancer, ▶imprinting, ▶isoform, ▶Rhabdomyosarcoma, ▶Denys-Drash syndrome, ▶Frasier syndrome, ▶acatalasemia; Hossain A, Saunders GF 2001 J Biol Chem 276:16817; Hammes A et al 2001 Cell 106:319.

Wilson Disease (WD): Recessive disease encoded in human chromosome 13q14.2-q14.3. It affects primarily persons of age 30 and above although juvenile forms have also been described. The major symptoms are cirrhosis of the liver and psychological ailments caused by a deficiency of ceruloplasmin resulting in copper accumulation. In this as well as other diseases

involving cirrhosis of the liver, at the upper and lower margin of the cornea (see Fig. W10) a greenish narrow ring (↑) occurs. The basic defect is in a copper transporting ATPase of the mitochondria. Inactivation of the enzyme (ATP7B or ATP7A) causes neurodegeneration and overexpression can lead to resistance to therapeutic drugs. Mutations in the N domain of the enzyme prevent tight ATP binding and can lead to >30 forms of Wilson disease (Dmitriev O et al 2006 Proc Natl Acad Sci USA 103:5302).

Figure W10. Wilson disease

XIAP (X-linked inhibitor of apoptosis) inhibits caspases and copper metabolism in WD and other copper toxicosis diseases. Intracellular copper alters the conformation of XIAP and lowers its ability to inhibit caspase. This results in sensitivity to apoptosis (Mufti AR et al 2006 Mol Cell 21:775). The prevalence of WD in the USA is about 3×10^{-5} . A similar anomaly has been observed in Long-Evans Cinnamon (LEC) rats that may serve as an animal model for the study of the disease. Prenatal diagnosis of offspring of carrier parents may be possible by using linkage with DNA markers. ▶Menkes disease, ▶acrodermatitis, ▶hemochromatosis, ▶mitochondrial disease in humans, ▶neurodegenerative diseases

Winged Helix Protein: This class of the helix-turn-helix proteins uses a β -hairpin (a wing) to bind the DNA. ▶DNA-binding protein domains; Gajiwala KS, Burley SK 2000 Curr Opin Struct Biol 10:110.

Wingless (wg/Dint-1; 2–30): *Drosophila* gene is involved in morphogenetic signaling and its homologs are found in all vertebrates and invertebrates. The mouse homolog is *Wnt*. Components of the *Wnt* cascade are altered in breast and colon cancers in mice and in human melanomas. The path of *Wg* function is depicted (see Fig. W11).

Fz (*fizzled trichomes*) and Dally (*division abnormally delayed*, controls heparan sulfate) are

Figure W11. Path of Wg function

G protein-like receptors. *Dsh* (*dishevelled*) mitigates the block by *Zw3* (*zeste white*), Armadillo is a β -catenin-like protein. *TCF* (*ternary complex factors*) co-activate transcription. Dsh protein blocks glycogen synthase kinase (GSK3) that would be a negative regulator of Armadillo. CK1 (a serine kinase, called casein kinase) phosphorylates Dsh~Zw. Actually, Wg is involved in more complex functions. Wg also signals to the epidermal growth factor (EGF) receptor. WNT-4 duplication in humans and mice masculinizes XX individuals. In the Sertoli and Leydig cells DAX1, an antagonist of SRY, is upregulated. The *Wnt* pathway is involved in signaling to somatic stem cells and the maintenance of cancer (Reya T, Clevers H 2005 Nature [Lond] 434:843). One study has revealed 238 potential regulators of the Wnt pathway and half of them have human orthologs and several of them are involved in human disease (DasGupta R et al 2005 Science 308:826). The secretion of Wnt ligand requires a transmembrane protein (Wentless [Wls]/Eveness interrupted [Evi]). *Wls* is in chromosome 3 of *Drosophila* within 68A/B band; homologs are present in the *Caenorhabditis* and human genomes (Bänziger C et al 2006 Cell 125:509; Bartscherer K et al 2006 Cell 125:523). ▶organizer, ▶EGF, ▶Armadillo, ▶adrenal hypoplasia congenital, ▶sex reversal, ▶catenins, ▶GSK, ▶TCF, ▶heparin sulfate, ▶morphogenesis in *Drosophila*, ▶zeste, ▶SRY, ▶Wolffian duct, ▶Gardner syndrome; Kühl M et al 2000 Trends Genet 16:279; Peifer M, Polakis P 2000 Science 287:1606; Wilkie GS, Davis I 2001 Cell 105:209; van de Wetering M et al 2002 Cell 109:S13; Peifer M, McEwen DG 2002 Cell 109:271; Mosimann C et al 2006 Cell 125:327; review: Clevers H 2006 Cell 127:469; <http://www.stanford.edu/~rnusse/wntwindow.html>.

Winner's Curse: A finance/business concept. In competitive bidding, the winner may be the loser. This may be the case when the highest bidder overestimates the value of an item/stock or any other object in a bidding competition (e.g., at an auction) and it turns out that, even if some preferential values are added, the value of the purchase is lower than estimated/expected.

A similar situation may be observed in population genetics when screening is conducted for a low expression, rare allele. Before the tests are carried out the frequency of carriers or homozygotes for the disease can be only guessed. If the size of the population studied is too small, the information gathered may not be reliable and useful. If a very large population is tested—at great expense—and the results are still ambiguous, the investment in labor and other means is not worthwhile. Thus, the winner (the thorough investigator) suffers the curse of being a loser. ▶game theory, ▶critical population size, ▶mutation rate; examples for winner's curse: <http://www.techcentralstation.com>.

Wiskott-Aldrich Syndrome (WAS, Xp11.23-p11.22): This X chromosomal immunodeficiency disease causes eczema, reduced platelet size, bloody diarrhea, greater susceptibility to infections, lymphocyte malignancies and usually death before the age of 10. The prevalence is about 4×10^{-6} . The affected individuals are deficient in a 115 kDa lymphocyte membrane protein and the platelets are abnormally low in a glycoprotein (sialophorin). Carriers may be identified by linkage, lymphocyte analysis and nonrandom inactivation of the X chromosomes. WAS is allelic to the human Xp11.23 thrombocytopenia gene. This gene includes 12 exons in 9 kb genomic DNA and encodes 502 amino acids. The involvement of CDC42 signaling defect is likely. Cdc42-GTP is a far better agonist for the protein WASP than Cdc4 2-GDP (Leung DW, Rosen MK 2005 Proc Natl Acad Sci USA 102:5685). The WAS protein (WASP) mediates cytoskeletal rearrangement and transcriptional activation of T cells. ▶immunodeficiency, ▶T cell, ▶cytoskeleton, ▶thrombocytopenia, ▶thrombopathic purpura, ▶cancer, ▶CDC42, ▶agonist, ▶podosome, ▶WASP, ▶platelet; Silvin C et al 2001 J Biol Chem 276:21450; Devriendt K et al 2001 Nature Genet 27:313; Caron E 2002 Current Opin Cell Biol 14:82.

Witkop Syndrome: ▶tooth-and-nail dysplasia

WL (working level): Used for the characterization of short-lived radon decay products in 1 liter of

air resulting in the ultimate emission of 1.3×10^{-5} MeV of alpha radiation energy. WL is also defined as 2.08×10^{-5} joule h m⁻³. WLM (working level/month) = exposure of 170 h at 1 WL. ►radon

WNT1 (cysteine-rich glucoprotein ligand): The ~18 vertebrate genes have numerous and diverse roles in signaling to development, particularly along the anterior-posterior body axis. ►INT1 oncogene in mouse, ►wingless gene product in *Drosophila*, ►morphogenesis in *Drosophila* {63}, ►pattern formation, ►organizer, ►Gardner syndrome, ►gonads; Skromme E, Stern CD 2001 Development 128:2915.

Wobble: The 5'-base of the anticodon can recognize more than one kind of base at the 3' position of the codon, e.g., both U or C in the mRNA may pair with G, and both G and A may pair with U, or A or U, or C may recognize I (inosinic acid at the 5'-position in the anticodon). There is no AAA anticodon for Phe but the GAA anticodon recognizes both UUU and UUC codons in the mRNA. The GUU and GUC codons of Val are decoded by an anticodon AAC. Inosinic acid occurs in the anticodon of 8 tRNAs of higher eukaryotes, in 7 of yeast and in the tRNA^{Arg}₂ of prokaryotes and plant chloroplasts. Inosine may be formed from adenosine by adenosine deaminases. In tRNAs, however, a different dimeric deaminase, encoded in yeast by *Tad2* and *Tad3* genes, is active. This deaminase is related to the cytidine deaminase (CDA). According to the classical or universal genetic code of 61 sense and 3 missense codons, a minimum of 32 tRNAs would be required to recognize all the amino acids. Further simplifications permit protein synthesis, however, by 22–24 tRNAs. In the human genome tRNA genes have been found all over the genome yet 140 tRNA genes are crowded in a 4 Mb region of chromosome 6. The altered mitochondrial code requires modifications in the anticodon wobble. ►genetic code, ►tRNA, ►anticodon, ►isoacceptor tRNA, ►mtDNA, ►hypoxanthine, ►decoding; Crick FHC 1966 J Mol Biol 19:548; Agris PF 1991 Biochemie 73:1345; Lim VI 1994 J Mol Biol 240:8; Sibley AP et al 1986 FEBS Lett 194:131.

Wolbachia: Refers to an endocellularly infectious group of bacteria of arthropods, nematodes and crustaceans that are transmitted maternally and may cause feminization, cytoplasmic incompatibility and thelytoky. *Wolbachia* is localized to the stem cell niche of *Drosophila* germarium (Frydman HM et al 2006 Nature [Lond] 441:509). Infected males cannot produce viable offspring with uninfected females because of cytoplasmic incompatibility. They are compatible, however, with infected females and produce offspring. In some *Culex* mosquitoes variations have been found in cytoplasmic incompatibility controlled

by two prophage genes of *Wolbachia* involving ankyrin repeats (Sinkins SP et al 2005 Nature [Lond] 436:257). Antibiotics can cure incompatibility in many instances. The removal of *Wolbachia* by antibiotics from parasitic wasps stops oogenesis. *Wolbachias* as endosymbionts of filarial nematodes are responsible for the river blindness disease (filariasis). *Wolbachia* infection of flies with some oogenesis defect causing *Drosophila* *Sex-lethal* alleles surprisingly restores fertility (Starr DJ, Cline TW 2002 Nature [Lond] 418:76). *Wolbachia* may serve as an agent to block the spread of malaria by causing sterility in the insect host (Ito J et al 2002 Nature [Lond] 417:452). There are several related species. The *W. pipientis* genome of 1,267,782 bp has been sequenced and it appears to contain an unusually high number of mobile elements as well as essential difference in metabolism compared to related species e.g., *Rickettsia* (Wu M et al 2004 PLoS Biol 2:327). ►cytoplasmic incompatibility, ►thelytoky, ►symbionts hereditary, ►segregation distorter, ►pronucleus, ►Rickettsia, ►ankyrin; Stouthammer R et al 1999 Annu Rev Microbiol 53:71; Zimmer C 2001 Science 292:1093; Dedeine F et al 2001 Proc Natl Acad Sci USA 98:6247; Saint André v A et al 2002 Science 295:1892; <http://troi.cc.rochester.edu/~wolb/FIBR/database.html>.

Wolcott-Rallison Syndrome (WRS, 2p12): Involves mutation in the translation initiation factor EIF2AK3. The recessive disorder affects neonatal or infantile insulin-dependent diabetes. Later, bone defects (epiphyseal dysplasia, osteoporosis), retarded growth, liver and kidney malfunction, mental retardation and heart disease may complicate the condition. ►EIF2

Wolf: (*Canis lupus*, 2n = 78), a carnivorous mammal, which can form fertile hybrids with domesticated dogs (*Canis familiaris*, 2n = 78) as well as with the coyote (*C. latrans*, 2n = 78) but not with foxes (*Vulpes vulpes*, 2n = 36). Domesticated dogs appear to be much closer evolutionarily to wolves (on the basis of mtDNA) than to coyotes. ►fox

Wolf-Hirschhorn Syndrome: A condition, which involves deletion (unequal crossing over, insertion) in one of the short arms of human chromosome 4p16.1 (usually the paternal) resulting in severe growth, mental, face and genitalia defects, etc. The deletion generally eliminates HOX7 (homeobox 7), responsible for normal development in humans and mice. Hemizygosity for the gene is sufficient for the disease. The severity of the disease is affected by alteration at adjacent sites (Bergmann D et al 2005 Trends Genet 21:188). ►deletion, ►hemizygous, ►homeobox, ►homeotic genes, ►Huntington's chorea; Näf D et al 2001 Am J Hum Genet 10:91; Zollino M et al 2003 Am J Hum Genet 72:590.

Wolffian Ducts: Develop as a precursor of the male gonads of vertebrates. This development is enhanced under the influence of testosterone hormone. The male gonad (testes) is formed by the Sertoli cells that eventually surround the spermatogonia. The Leydig cells (Yao H-C et al 2002 *Genes Dev* 16:1433) secrete the steroid testosterone and the Sertoli cells produce the anti-Müllerian hormone (human chromosomal location 12q13), which causes regression of the uterus and the Fallopian tubes. ►gonads, ►Müllerian ducts, ►DSS

Wolf-Parkinson-White Syndrome: A heart disease with a short P and a long QRS phase of electrocardiography. It is also called preexcitation syndrome because the heart ventricles are excited prematurely. It may cause increased palpitations and sudden death. The causes are complex; dominant defects at chromosome 7q3 have been implicated and a mitochondrial component may also be involved. ►electrocardiography, ►mitochondrial diseases in humans [Leber hereditary optic dystrophy].

Wolfram Syndrome (DIDMOAD): Mutation in human chromosome 4p16.1 gene encoding a ~100 kDa transmembrane protein involves diabetes insipidus, diabetes mellitus, optic atrophy and deafness. It has been proposed that a large mitochondrial deletion extending over several coding sequences (7.6 kb) is responsible for these diseases but it has not been confirmed. ►diabetes, ►optic atrophy, ►deafness, ►mitochondrial diseases in humans; Strom TM et al 1998 *Hum Mol Genet* 7:2021.

Wolman Disease (lysosomal acid lipase deficiency): A condition due to autosomal recessive genes in the long arm of human chromosome 10q24-q25 and in mouse chromosome 19. The early onset forms are due to a deficiency of this enzyme (cholesteryl ester hydrolase) and are characterized by liver and spleen enlargement, failure to feed normally and death by the age of 2 to 4 months. The accumulation of cholesterol esters is caused by mutant alleles of the same locus. In some forms survival is till the teens. ►cholesterol, ►lysosomes, ►lipase; Du H et al 1998 *Hum. Mol. Genet* 7:1347.

Woodchuck: ►*Marmota monax*

Woodrats: There are many species mainly with $2n = 52$.

Woods' Light: Refers to an ultraviolet light source with nickel oxide filter and with a maximal transmission at about 365 nm while most other spectral regions are blocked. ►ultraviolet light

Woolly Hair: This may be black (and autosomal dominant) or blond (and autosomal recessive). In both cases, the hair is short and tightly curled.

Wordmatch: Finds exact matches of a given size between two protein sequences. (<http://ocgc.ca/programs/emboss/wordmatch.html>).

Working Hypothesis: This is an experimentally testable assumption regarding a problem.

Worm Genetics: An informal reference to *Caenorhabditis elegans*. ►*Caenorhabditis*

Woronin Bodies: These occur around fungal pores supposedly to protect against excessive leakage if the cells are damaged. (See Tenney K et al 2000 *Fungal Genet Biol* 31:205).

Wortmannin: A protein from *Penicillium fumiculosum*/*Talaromyces wortmanni* which is a stimulator of neutrophils and inhibitor of PIK, DNA-PK and thus inhibits the repair of double-breaks in the DNA (see Fig. W12). Wortmannin modulates the phosphatidylinositol metabolic pathway. ►neutrophil, ►PIK, ►DNA-PK, ►phosphatidylinositol; Wang H et al 2001 *Nucleic Acid Res* 29:1653.

Figure W12. Wortmannin

Woude Syndrome: ►van der Woude syndrome

Wound Healing: Requires angiogenesis, which can be provided by administering angiogenic proteins such as vascular endothelial growth factor (VEGF) or placental growth factor. To ensure a stabilizing effect, the delivery of multiple growth factors may be helpful. Hypoxia-inducible factor (HIF) can stimulate angiogenesis. HIF-1 heterodimer has two subunits α and β . The former has an oxygen-sensitive degradation domain (ODD). This domain is prolyl hydroxylated in an oxygen-dependent manner and can bind the von Hippel-Lindau protein and consequently the HIF-1 α subunit is degraded by the proteasome under normal oxygen tension. Under hypoxia, HIF-1 α can heterodimerize with HIF- β and upon entering the nucleus it induces gene expression. The prevention of HIF- α degradation or its overexpression results in nuclear translocation and VEGF expression under normal oxygen level. If the ODD domain is removed, VEGF and other genes are upregulated. In a specially engineered vector complex on a fibrin surgical matrix, entrapped in a DNA nanoparticle delivered to the dermal wound of mice resulted in potent therapeutic

effects (Trentin D et al 2006 Proc Natl Acad Sci USA 103:2506). The disruption of the epithelial cell layer generates endogenous electric field and cell migration. Phosphatidylinositol-3-OH kinase- γ and PTEN genes are essential for electrical signal-induced cell migration and wound healing (Zhao M et al 2006 Nature [Lond] 442:457). ▶tissue engineering, ▶phosphoinositides, ▶PTEN, ▶von Hippel-Lindau syndrome, ▶VEGF, ▶angiogenesis

Wound-Healing Assay: Used to analyze cell migration. A confluent mammalian cell monolayer is scratched by a blunt pipette tip and the “wound” so generated heals by cell migration, which can be monitored by automatic devices (Todaro GJ et al 1965 J Cell Physiol 66:325). It also detects the metastatic ability of neoplasias (see Fig. W13). ▶metastasis, ▶neoplasia

Figure W13. Wound-healing time course

Wound Response: Upon wounding one leaf physiological changes take place in other parts of the plant body and the expression of proteinase inhibitors (Pin) is triggered by glycan, jasmonate and peptide signals. The 18-amino acid peptide signal, systemin, in tomato plants, wounded by herbivorous insects, stimulates proteinase expression. Salicylic acid may block the wound response. Wounding of plants may also induce a large number of genes of different function. The plants may produce peroxides against the microbes infecting the wounds. Phenolics may accumulate, photosynthesis may be reduced and ethylene biosynthesis may be induced. ▶glycan, ▶jasmonic acid, ▶insect resistance in plants, ▶host-pathogen relationship, ▶phenolics, ▶ethylene; Zhou L, Thornburg R 1999, p 127. In: Reynolds PHS (Ed.) Inducible Gene Expression In Plants. CAB, New York.

Wrapping Choice: A generalized transducing phage “chooses” to scoop up the host rather than the viral DNA and “wraps” it into the phage capsid. ▶transduction

Wright Blood Group: A very rare blood group; the frequency of the Wr(a) antigen is about 3×10^{-4} in Europe. ▶blood groups

Wright-Fisher Model: ▶genetic drift, ▶drift genetic

Wrinkled/Smooth: This is a gene locus of pea, immortalized by Mendel’s discovery of monogenic inheritance. The recessive “wrinkled allele” turned out to be an

insertional mutation. ▶pea for photograph of wrinkled and smooth seeds.

Writhing Number: This indicates the contortion of a DNA double helix in a supercoiled state. It measures the helix axis in space. ▶linking number; Kobayashi S et al 2001 Chem Pharm Bull Tokyo 49:1053.

Wrod Score (wrong lod score): Obtained when a linkage is estimated as lod scores on the assumption of an incorrect genetic model (ϕ). The genetic model in complex traits may easily be misspecified. ▶lod score, ▶mod score, ▶model genetic; Hodge SE, Elston RC 1994 Genet Epidemiol 11(4):329.

Wrongful Birth: Potential responsibilities of a physician or a genetic counselor for negligence in informing or prenatal care of prospective parent(s) about risks involving childbirth. (See Randall KC 1979 Hofstra Law Rev 8:257).

Wrongful Life: A potential responsibility of parents, physicians and genetic counselors for not preventing the birth of a child with a serious hereditary disease or in the case of illegitimacy, which may carry a social stigma. The affected offspring may sue. ▶counseling genetic, ▶genetic privacy, ▶confidentiality, ▶paternity test; Foutz TK 1980 Tulane Law Rev 54:480.

WW Domain: A two-tyrosine motif (38–40 amino acids) of signaling proteins and a binding site for proline-rich peptides. The binding of a WW domain by Pin1 and Nedd4 proteins apparently does not require prolines for binding, rather the WW domains are binding sites for phosphoserine and phosphothreonine. Among the many diverse proteins, their ligands include Cdc25C phosphatase, microtubule associated tau, carboxy-terminal of RNA polymerase II, etc. ▶SH2, ▶SH3, ▶pleckstrin, ▶PTB, ▶signal transduction, ▶Pin1; Nedd Sudol M, Hunter T 2000 Cell 103:1001.

www (world wide web): The system is available through the Internet with the aid of a browser program, which makes possible the search through a computer linked to the system. ▶Internet, ▶HTML

wx Gene (waxy): Occurs in various cereal plants and is used as a chromosome marker (in the short arm of chromosome 9–56 of maize). In the presence of the dominant allele starch is formed (stained blue by iodine stain). If it is replaced by recessive allele, amylopectin is formed (stained red-brown) because of a defect in NDP-starch glucosyltransferase. ▶iodine stain, ▶amylopectin, ▶TILLING

Historical vignettes

Edith Kramer 2002 American J Art Therapy 40(4):218

“How can we characterize [the opposite of kitsch] good art? Three elements seem essential; evocative power, inner consistency, and an economy of means so that the quality of the work would be diminished if anything would be added or omitted.”

Apparent mutations were recorded by the ancient literature. Aristotle says, “whoever does not resemble the parent is, in some respects, a monster, because in this case nature has deviated, to a certain degree, from the hereditary type” (*Generation of Animals*, Book IV, Part 3, Para. 1).

In 1844 WH Prescott retells the *History of the Conquest of Mexico* (Dutton, New York): “I must not omit to notice a strange collection of human monsters, dwarfs, and other unfortunate persons, in whose organization Nature had capriciously deviated from her regular laws. Such hideous anomalies were regarded by the Aztecs as a suitable appendage of state. It is even said, they were in some cases the result of artificial means, employed by unnatural parents desirous to secure a provision for their offspring by thus qualifying them for a place in the royal museum.”

Thus even induced mutation had been anticipated much before it had been experimentally demonstrated by HJ Muller and LJ Stadler in the mid 1920s.

X

x: Refers to basic chromosome number. ▶ [polyploids](#), ▶ [n](#)

\bar{x} : Denotes the arithmetic mean of the sample.

X: A symbol for crossing over or chiasma.

χ^2 : ▶ [chi square](#)

X¹⁷⁷⁶ (bicentennial): A bacterial strain with an absolute requirement for diaminopimelic acid (a lysine precursor) and needed for the growth of viable bacteria, and therefore it cannot survive outside the laboratory. It was so named in the US bicentennial year at the Asilomar Conference in 1976. ▶ [Asilomar Conference](#)

X Element: ▶ [chi elements](#)

Xa: A blood coagulation factor. It is also a plasmid factor that specifically cleaves protein after Arg of the tetrapeptide Ile-Glu-Gly-Arg that connects the 31 amino terminal of phage λ cII protein. ▶ [clotting](#), ▶ [lambda phage](#); Verner E et al 2001 J Med Chem 44:2753.

Xanthine: A purine derived from either adenine through hypoxanthine by xanthine oxidase or from guanine by deamination (see Fig. X1). By xanthine oxidase it is converted to uric acid. ▶ [uric acid](#)

Figure X1. Xanthine

Xanthinuria (XDH, 2p23-p22): Refers to a recessive, xanthine dehydrogenase/oxidase deficiency resulting in the excretion of excessive amounts of xanthine and xanthine stones in the kidneys. The uric acid content of the urine and serum is reduced. The 36-exon gene spans ~60 kb DNA. ▶ [kidney diseases](#), ▶ [uric acid](#)

Xanthoma Cell (foam cell): Highly vacuolated because of excessive amounts of lipids.

Xanthomatosis: ▶ [cerebral cholesterinosis](#)

Xanthophyll: Refers to yellow carotenoid pigments that play an accessory role in light absorption. ▶ [photosystems](#); Ruban AV et al 2001 J Biol Chem 276:24862.

X-Box: The sequence—with some variations—of the X-boxes widely present in eukaryotes: GTTTCAT-GGAAAC. Using stringent criteria for X-boxes within 250 bp upstream of the start codon, 293 genes have been identified in *Caenorhabditis* (Chen N 2006 Genome Biol 7:R1216). X-box binding protein (XBP-1) is a transcription factor essential for hepatocyte growth, differentiation of cilia as well as for plasma cell differentiation. Overexpression of XBP-1 has been reported in breast cancer and other carcinomas (Fujimoto T et al 2007 Anticancer Res 27(1A):127). XBP1 has evolved a mechanism for “on-demand” switching of translation between two overlapping reading frames but it can provide functionality to both reading frames (Nekrutenko A, He J 2006 Trends Genet 22:645).

XBP: Encodes the 89 kDa subunit of human transcription factor TFIIF, corresponding to yeast *SSL2*, encoding a 105 kDa polypeptide. XBP-1 is required for the differentiation of plasma cells into B lymphocytes. ▶ [transcription factors](#), ▶ [B lymphocytes](#)

X2BP: MHC-II promoter binding protein, along with NF-Y and RFX. ▶ [RFX](#), ▶ [MHC](#); Reimold AM et al 2001 Nature [Lond]:412:300.

X Chromosomal Inactivation: ▶ [lyonization](#), ▶ [Barr body](#), ▶ [dosage compensation](#), ▶ [Xic](#)

X Chromosome: One of the sex chromosomes generally present in two doses in females and in one in males. The mammalian X chromosome developed from autosomes ~300 million years ago. In some species females are XY whereas in males either XX or XO or other chromosomal doses may be found. In species where the female is heterogametic, her sex chromosomal constitution is often designated as WZ and that of the male as ZZ. The sex chromosomes of the semi-aquatic, duck-billed platypus (*Ornitorhynchus anatinus*, 2n = 56), an egg-laying Australian mammal, share genes with the bird's Z chromosomes and the mammalian X (Grützner F et al 2004 Nature [Lond] 432:913). Sex chromosomes apparently evolved from autosomes. The PAR (pseudoautosomal) region is a relic of autosomal origin. It is assumed that the X chromosome underwent substantial evolution in humans and sequences fairly well conserved in other mammals but display only small homology with the bird's Z chromosome. Some of the genes were acquired from autosomes, other genes were retained or transposed to autosomes because even in males (with only one X) two doses were required for certain

developmental processes. Initially, in humans 1,098 genes (7.1/Mb) and 700 pseudogenes (4.6/Mb) have been revealed in the X chromosome.

More recent analysis has revealed 696 protein-coding genes and 652 X-linked and 432 X-derived pseudogenes. About 5% of the pseudogenes displayed some transcripts, indicating their role in genetic regulation. On an average, the pseudogenes differed from the parental gene by 70 changes/1,000 nucleotides. New exons were detected in 22% of the genes and 35% displayed exon skipping. Of the earlier reported 142 putative non-coding RNAs, 64 (44%) were untranslated segments of known genes (Harsha HC et al 2005 Nature Genet 37:331). Slightly different conclusions were reached by another contemporaneous publication (Ross MT et al 2005 Nature [Lond] 434:325).

The gene density and gene size is generally smaller than in the autosomes although the largest human gene, the muscular dystrophy gene is X-linked. The frequency of CpG islands is about half in the X compared to the genome average. Approximately 10% of the so-called cancer-testis antigens are in the human X chromosome. The cancer-testis antigens are specifically expressed in many different types of cancer cells (see e.g., MAGE). Apparently 153,146 single nucleotide polymorphisms occur in the X chromosome. The euchromatic part of the X chromosome contains 57% interspersed repeats versus 45% of the genome average. The L1 family constitutes 29% of the X versus only 17% of the genome average. Several human diseases are associated with deletions or inversion in X chromosomal duplications. There is a relatively longer 2.7 Mb pseudoautosomal (PAR1) and a shorter 330 kb PAR2 region shared with the Y chromosome where recombination can occur, but in some other homologous regions (XAR) there is no recombination between X and Y. The latter types can be mapped only by radiation hybrids. Only 54 of the annotated X chromosomal genes display homologies with Y. In the PAR1 region there are 24 and in PAR2 5 genes that may recombine. The latter ones are located in three groups on both sex chromosomes but they do not recombine. About 15 of the protein-coding Y chromosomal genes lack homologies in the X chromosome. The human X chromosome has lower variability (~60%) than the autosomes. Both human and mouse X chromosomes show very close synteny. One or more of the double (or multiple) X chromosome(s) of mammals are inactivated early in female development. Yet more than 15% of the genes escape inactivation (Ross MT et al 2005 Nature [Lond] 434:325). ▶Y chromosome, ▶chromosomal sex determination, ▶dosage compensation, ▶Barr body, ▶lyonization, ▶Ohno's law, ▶monotrene, ▶pseudoautosomal, ▶sex chromosome, ▶autosome,

X Chromosome Counting: This mechanism is used for sex determination in the case of XX versus XO. The *xol-1* gene of *Caenorhabditis* constitutes a switch mechanism that specifies male developmental course if it is inactive. In XX nematodes *xol-1* is repressed post-transcriptionally or the RNA-binding protein encoded by the *fox-1* gene reduces its level of expression. The transcription of gene *xol-1* is suppressed primarily by SEX-1 hormone receptor protein, which binds to the promoter in XX nematodes. ▶sex determination, ▶chromosomal sex determination, ▶dosage compensation; Maxfield Boumil R, Lee JT 2001 Hum Mol Genet 10:2225.

X Chromosome Inactivation: ▶lyonization, ▶Xic

XCID: X chromosome-linked severe combined immunodeficiency. ▶SCID, ▶immunodeficiency

xDNA (expanded DNA): Differs from the natural DNA double helix in that some of the natural bases are expanded by a benzene ring (B, red) and, therefore, the molecule is broader (A: adenine [purple], T: thymine [blue]) (see Fig. X2). Besides the bases shown, the others (C and G) can also be expanded; the sugar-phosphate backbone is omitted for the sake of simplicity. The designed duplex is right-handed and antiparallel, and hydrogen-bonded in a way analogous to that of Watson-Crick DNA. The sugar-phosphate backbone adopts a regular conformation similar to that of B-form DNA. The xDNA can encode more information than the natural one because it can use 8 instead of 4 nucleotides. It is more heat resistant than the natural DNA and it fluoresces. This property may make it useful for the detection of genetic defects. ▶base analogs, ▶hydrogen pairing, ▶Watson and Crick model, ▶DNA types; Kool ET 2002 Acc Chem Res 2002 35(11):936; Liu H et al 2003 Science 302:868; Lynch SR et al 2006 J Am Chem Soc

Xenia: This is the expression of the gene(s) of the male in the endosperm (e.g., purple) following fertilization; the expression in the embryo may not yet be visible (see Fig. X3). ▶*metaxenia*

Figure X3. Xenia

Xenobiotics: Refers to compounds that do not naturally occur in living cells. They are often toxic or harmful substances.

Xenogamy: Meaning fertilized by different neighboring plants.

Xenogeneic: Refers to transplantation from another species (xenotransplantation). ▶*allogeneic*

Xenogenetics: The study of the effect of environmental factors on conditions under polygenic control. ▶*polygenic*

Xenograft: Refers to the transplantation of tissue from another species (e.g., animal→human). It poses problems of rejection and the likelihood of viral infection (e.g., porcine endogenous proviruses [PERV]) as well as the emergence of new diseases. The complement cascade of the immune system mediates the rejection. If swine, transgenic for the human complement, is used as a heart donor to baboons, the function of the heart is prolonged by several hours. The limited clinical evidence, however, does not indicate substantial risk in pig→human grafts. ▶*complement*, ▶*immune system*, ▶*transgenic*, ▶*epitope*, ▶*xenotransplantation*, ▶*gene therapy*, ▶*αGT*, ▶*PERV*; Matsunami K et al 2001 Clin Exp Immunol 126:165.

Xenology: A study of the combination of original and foreign genetic sequences within an organism or a group of organisms caused by horizontal transfer and transformation. ▶*homology*, ▶*transmission*, ▶*transformation*, ▶*infectious heredity*, ▶*orthologous loci*, ▶*paralogous loci*; Gogarten JP 1994 J Mol Evol 39:541.

Xenopus (*X. laevis*, South African clawed toad, $2n = 4x = 36$, DNA 3.1×10^9 bp): This is a species of frogs.

Being tetraploid and having a long generation time of several years does not make it a favorite object of genetic manipulations although it is an excellent object of embryological studies. The oocyte may reach 1.5 mm in size and it is thus visible by the naked eye and lends itself to various manipulations. Pioneering research was conducted with nuclear transplantation. Transformation of embryonic tissues was not as successful as expected because too few cells expressed the transgenes. Now techniques have been developed for transformation of sperms, and this will permit the study of dominant transgenes on various developmental and physiological processes. *Xenopus* (*Silurana*) *tropicalis* is the only diploid species (1.7×10^9 bp, generation time 4–6 months) but it is somewhat distantly related. *X. tropicalis* is very prolific (1,000–3,000 eggs per ovulation) and transformation is very efficient. ▶*toad*, ▶*frog*, ▶*transformation*, ▶*transgene*, ▶*Xenopus oocyte culture*; genetic regulatory networks in embryonic development: Koide T et al 2005 Proc Natl Acad Sci USA 102:4943; <http://www.dkfz-heidelberg.de/abt0135/axeldb.htm>; <http://www.nih.gov/science/models/>; <http://www.tigr.org/tdb/tgi/>.

Xenopus Oocyte Cultures: *Xenopus* frog oocytes are about 1 μ L in volume. They contain large amounts of DNA (12 pg in the nucleus, 25 pg in the nucleoli, 4 ng in the mitochondria). They can synthesize daily 20 ng of RNA and 400 ng of protein. About 10^6 to 10^7 bp DNA can be directly injected into the *germinal vesicle* (the nucleus). The injected DNA is packaged into the nucleosomal structure, and it is replicated and translated by the cellular machinery and the products are ready for analysis within a few hours. Recombinant DNA can be introduced and studied the same way. Exogenous DNA is replicated according to the cell cycle of the oocytes and no re-initiation of the foreign DNA replication occurs. All foreign DNAs are replicated according to the oocyte cell cycles and all the foreign replicational signals are overridden. Replication in the oocytes also is extremely rapid because transcription is halted during replication. *Xenopus* oocytes have been very successfully used for the structural, morphological analysis of vertebrate embryogenesis. They have proved to be extremely useful for the molecular analysis of transcription, regulation, cell-to-cell communication and early morphogenesis. ▶*oocyte*, ▶*protein synthesis*, ▶*morphogenesis*; Romero MF et al 1998 Methods Enzymol 296:17.

Xenorhabdus: *X. nematophila* is the best understood of the five identified species of *Xenorhabdus*. The bacterium colonizes the intestine of a non-feeding stage of *Steinernema carpocapsae* nematodes. The nematode is the vector that shelters the bacteria

from the competitive soil environment, and shuttles *X. nematophila* into insect hosts. The bacterium functions as a potent pathogen that infects and kills diverse insect species, which serve as the nutrient source for the development and reproduction of the nematode. Some *Xenorhabdus* species produce effective antibiotics against plant and animal pathogens. ► *Caenorhabditis*; Goodrich-Blair H, Clarke DJ 2007 Mol Microbiol 64:260.

Xenotransplantation: Refers to the transplantation of organs/tissues among different species and may involve the potential danger of transferring new viruses. On the other hand, xenotransplantation may have potentials in curing disease, e.g., the use of resistant baboon livers in the case of hepatitis B infections and baboon bone marrow for AIDS victims. The transplanted foreign cell or tissue may not function in the recipient or stimulate an adverse immune reaction. The transplanted tissue may incite the complement within minutes in hyperacute rejection. In some instances the reaction may be delayed for weeks but an acute vascular rejection may follow by interaction of the xenoreactive antibodies with the donor blood vessels. Galactose α -1,3-transferase knockout lines may overcome the immune reaction of the recipient against the graft but does not entirely solve the problem because the antibodies may attack other antigens. Genetically modified heme oxidase (HO-1) may provide some protection but it may generate toxic side effects (oxidant, bilirubin). The modification of the recipient antibodies against the transplant by genetic engineering may come into consideration. Also, e.g., the pig donor may be modified by human gene knock-ins. The porcine endogenous retrovirus (PERV) and some as yet unknown viruses may pose great risks not only to the recipient, but more importantly to the human populations also. Deleting the virus or inactivating them may become a means of protection. More research is required in this field. ► *xenogeneic*, ► *xenograft*, ► *immune tolerance*, ► *immunosuppression*, ► *grafting in medicine*, ► *rejection*, ► *baboon*, ► *hyperacute reaction*, ► *α GT*, ► *knock-in*, ► *PERV*, ► *OBA*, ► *microchimerism*, ► *1,3-galactosyl-transferase α* ; Sim KH et al 1999 Can J Gastroenterol 13:11; Lai L et al 2002 Science 295:1089; Cooper DKC et al 2002 Annu Rev Med 53:133; <http://www.fda.gov/cber/gdlns/clinxeno.htm>.

Xenotropic Retroviruses: These are replicated only in the cells of species other than the species from which the virus originated. ► *ecotropic* and *polytropic virus*

Xeroderma Pigmentosum (XP): The primary symptoms may develop during the first year of life as extremely pronounced freckles induced by sunshine proliferate and appear as skin cancer (see Fig. X4). In some cases

the central and peripheral nervous systems are also affected. Usually A (9q22.2-q31), B (2q21), C (3p25), D (19q13.2-q13.3), E (11p12-p11), F (16p13.2-p13.1) and G (13q32-q33) types are distinguished, the other complementation groups (H and I) are less clear. Complementation group A encodes DNA damage binding protein B, and D codes for helicases, C initiates global nucleotide excision repair and selectively repairs cyclobutane pyrimidine dimers rather than 6–4 photoproducts. The XP-D gene product is a subunit of the TFIIH transcription factor and it is regulated by vitamin D receptor-responsive genes (Drané P et al 2004 Mol Cell 16:187). XPC is homologous to yeast genes RAD23A and B and it is sometimes referred to as XPC-HR23A and B. Types F and G are defective in a DNA repair endonuclease (homologous to yeast RAD1).

Figure X4. A mild form of xeroderma pigmentosum. The initial signs are usually very heavy freckles that gradually develop into different types of skin cancer. The progress of the disease is enhanced by sunshine. A variety of ailments may accompany the main symptoms and the afflicted persons rarely reach adulthood. (Courtesy of the March of Dimes—Birth Defects Foundation)

One type of XP, XP-V patients, representing about 25% of the clinical cases of the disease, do not have a defect in nucleotide exchange repair and are not sensitive to UV radiation. In such cases the defect is caused by failure of replication of the leading strand through pyrimidine dimers. The replication (by polymerase ζ) of the lagging strand associated with the photoproduct can slowly proceed and results in an asymmetrical replication fork with an extended single strand leading strand of the parental DNA molecule. Unfortunately, pol ζ is error prone and the error-free pol η (encoded by *RAD30*) is defective in XP-V individuals. Humans have two homologs of *RAD30*.

As a consequence the patients' cells become susceptible to mutation and carcinogenesis.

Another form involving milder symptoms is also known which has an apparently dominant inheritance. In some forms the defect is not in excision repair but a post-replicative anomaly causes light sensitivity. Similar gene(s) occur(s) in mouse and five *RAD* genes of yeast also have defects in excision repair. ▶DNA repair, ▶excision repair, ▶Bloom syndrome, ▶ataxia telangiectasia, ▶Fanconi syndrome, ▶Cockayne syndrome, ▶*RAD*, ▶light-sensitivity diseases, ▶thrichothiodystrophy, ▶helicase, ▶complementation groups, ▶DDB, ▶DNA polymerases, ▶ultraviolet-sensitivity syndrome, ▶cyclobutane dimer, ▶pyrimidine-pyrimidinone photoproduct, ▶5',8-purine cyclodeoxynucleosides, ▶transcription factors, ▶vitamin D; Bootsma D et al 1998, p 245. Xerophyte: A draught-tolerant plant which thrives in low precipitation regions.

X-Family of DNA Polymerases: pol β -like nucleotidyl-transferases. Pol λ is similar to pol β . TdT is a non-templated polymerase of immature lymphocytes in the bone marrow. Pol μ is homologous to TdT. TdT promotes diversity in non-homologous end joining (HEJ). Pol μ and Pol λ are also involved in NHEJ (Nick McElhinny SA et al 2005 Mol Cell 19:157). Pol σ is a templated or non-templated enzyme establishing sister chromatid cohesion. ▶DNA polymerases, ▶nucleotidyl-transferase, ▶NHEJ; Aravind L, Koonin EV 1999 Nucleic Acids Res 27:1609; Rattray AJ, Strathern JN 2003 Annu Rev Genet 37:31.

XG (Xg[a]): A blood group antigen determining dominant factor in the short arm of the human X chromosome. It appears that this end of the X chromosome can recombine with the Y chromosome, and it does not undergo lyonization like the majority of the X chromosomal genes. ▶lyonization, ▶blood groups, ▶ichthyosis; Fouchet C et al 2000 Immunogenetics 51(8–9):688.

Xgal (5-bromo-4-chloro-3-indolyl- β -D-galactopyranoside): When β -galactosidase enzyme hydrolyzes this chromogenic substrate blue color is formed in a bacterial culture plate. ▶ β -galactosidase

XIAP: A caspase inhibitor which is a member of the human IAP family of proteins. ▶IAP, ▶caspase; Riedl SJ et al 2001 Cell 104:791.

XGLD: Denotes poly(A) polymerase. ▶symplekin

Xic (X chromosome inactivation center, Xq13.2): Its effect is somewhat similar to but unlike *Xist*, which

has a fairly localized cis effect, *Xic* extends globally on the X chromosome. *Xic* delays the replication of the X chromosome and mediates the hypoacetylation of histone 4 and contributes to heterochromatinization of that chromosome. *Xic* controls chromosome counting in dosage compensation and selects one or more of the X chromosomes for inactivation. In case there is a short transient pairing between two normal X chromosomes, which both carry the *Xic* locus, the inactivation of the X chromosomes is random. In case *Xic* and *Tsix* are deleted, X chromosome inactivation may become erratic, i.e., either it does not take place at all or both are inactivated or one is inactivated and the other is not. In case an additional copy of *Xic* is introduced by transformation and the two X chromosome cannot pair at the *Xic* site then neither of the two X chromosomes is inactivated (Carrel L 2006 Science 311:1107; Xu N et al 2006 Science 311:1149). ▶lyonization, ▶*Xist*, ▶methylation of DNA; Prissette M et al 2001 Hum Mol Genet 10:31.

XID: Refers to sex chromosome-linked immunodeficiency. ▶scid, ▶immunodeficiency

Xist (X chromosome inactive sequence transcript at Xq13.2; antisense of *XIST* is *TSIX* at Xq13.2): This gene has no protein product but its 15-kb RNA covers the genes of the inactive mammalian X chromosome beginning from the *Xic* site (Xq13.2). The *Xist* RNA gene evolved only in placental mammals by pseudogenization (functional relaxation) of a protein-coding gene (Duret L et al 2006 Science 312:1653). Deletion analysis demonstrates that the first exon of human *XIST* is sufficient for both transcript localization and the induction of silencing and that, unlike in mice, the conserved repeat region is essential for both functions. This indicates that there is a difference in inactivation between humans and mice (Chow JC et al 2007 Proc Natl Acad Sci USA 104:100104).

Underacetylated histones, methylated CpG islands and late replication of the DNA cause inactivation of the X chromosome. *Xist*-triggered inactivation is preceded by methylation of histone-3 at lysine 9. *Xist* acts in cis and may also be expressed in autosomes or in transgenes inserted in the autosomes and affect the neighboring genes. Since the X chromosomal inactivation is restricted to the copies of the X chromosome present more than once, it has been suggested that *Xist* counts (senses) X chromosomal dosage. Deletions downstream of *Xist* make it constitutive, i.e., it is expressed and causes inactivation of the X chromosome concerned. From 15 kb downstream location a 40 kb apparently antisense RNA *Tsix* is transcribed across the *Xist* locus in both X chromosomes of diploids until the determination of inactivation. Prior to the onset of the inactivation *Tsix* is transcribed in an antisense orientation only on the

X chromosome destined for inactivation and it is shut down again after the inactivation begins. Apparently, *Tsix* determines the selection of the X chromosome for inactivation by the *Xce* controlling element without affecting the silencing itself. Knockout of the paternal *Tsix* does not affect embryonal development. If the *Tsix* knockout is transmitted through the female, embryos of both sexes die because both X chromosomes are silenced in the female offspring and the single X in males. The role of *Tsix* in humans and mice is debated. The site *Xite* promotes *Tsix* persistence on the active X chromosome (Ogawa Y, Lee JT 2003 Mol Cell 11:731). In X chromosome: autosome translocations the inactivation is inefficient because the spreading of the inactivating signal is not favored by the chromatin structure (Popova BC et al 2006 Proc Natl Acad Sci USA 103:7706). It has been reported that the breast cancer gene BRCA1 alters the Xist function but this finding has not been confirmed (Xiao C et al 2007 Cell 128:977), it was, however, substantiated later (Silver DP et al 2007 Cell 128:991). ▶[lyonization](#), ▶[Xic](#), ▶[dosage compensation](#), ▶[histones](#), ▶[imprinting](#); Lee JT 2000 Cell 103:17; Matsui J et al 2001 Hum Mol Genet 10:1393; Migeon BR et al 2001 Am J Hum Genet 69:951;

X-Ray Caused Chromosome Breakage: The major effects of ionizing radiations on living cells are chromosome breakage (see Fig. X6). Chromosome breakage has been extensively utilized for the genetical analyses of knocking out genes, the production of radiation hybrids, deletion mapping, genomic subtraction, etc. The destructive effects of the radiation depend on the nature of radiation. Soft X-rays having higher density of linear energy transfer, break the chromosome more effectively than the shorter wavelength and high-energy hard X-rays. The destructive effect also depends on the species exposed, the type of tissues irradiated, the physiological conditions during the delivery of the radiation, the repair system, etc. In *Drosophila* and locusts usually 1000 – 5000 R doses are employed for chromosome breakage in adults and embryos. In the case of gonadal radiation, 100 to 500 R may be effective. In the testis cells of *Macaca mulatta* monkey an increase of radiation dose from 25 R to 400 R resulted in close to exponential increase of chromosome breakage reaching about 1.5% of the chromosomes at the highest dose. In the large nuclei and chromosomes of *Trillium* and *Vicia faba* generally 100 to 500 R break the root tip chromosomes and lower doses may be sufficient if applied to pollen mother cells. For the smaller nuclei of maize 800 to 1500 R

may be chosen. The very small somatic nuclei of *Arabidopsis* may tolerate 5–10 fold higher doses of irradiation than maize. ► [radiation sensitivity](#), ► [radiation hazard assessment](#), ► [radiation effects](#), ► [LET](#), ► [radiation hybrid](#), ► [cathode rays](#); Brinkley BR, Hittelman WN 1975 Int Rev Cytol 42:49.

X-Ray Crystallography: ► [X-ray diffraction analysis](#)

X-Ray Diffraction Analysis: Used for the analysis of the structure of molecules by determining the angles of electron scattering upon exposure to X-rays. When a large number of a particular type of molecules in an array is irradiated they scatter the incident electrons. Where the scattered beams cancel each other, no bright image is formed. Where however the scattered electrons reinforce each other because they diffracted by a certain common arrangement of crystals or molecules, a bright image is formed on the screen. Thus, the intensity of the spots on the screen provides a basis for calculating and determining the internal, three-dimensional structure of the object. ► [nuclear magnetic resonance spectrography](#), ► [X-rays](#); <http://www.rcsb.org/pdb/>.

X-Ray Hazard: ► [X-ray](#), ► [radiation hazard assessment](#), ► [radiation protection](#), ► [radiation effects](#), ► [X-ray caused chromosome breakage](#)

X-Ray Repair: Involves excision repair mechanisms. A human X-ray repair gene locus has been isolated through complementation of excision repair-deficient Chinese hamster ovary cells by human DNA. XRCC2 repairs DNA double-strand breaks by homologous recombination. The locus XRCC1, encoding a ligase III polypeptide, has been assigned to human chromosome 19q13.2-q13.3. XRCC4 locus (human chromosome 5) is involved in the determination of X-ray sensitivity in the G1 phase of the cell cycle but its response in the S phase appears normal, indicating that the defective mutants (in Chinese hamster ovary cells)

are deficient in the repair of DNA double strands. The XRCC9 allele is in the FANC-G complementation group of Fanconi anemia. ▶radiation sensitivity, ▶excision repair, ▶DNA repair, ▶physical mutagens, ▶X-rays, ▶Fanconi anemia, ▶X-ray caused chromosome breakage, ▶XRCC, ▶NHEJ, ▶XLF; Tebbs RS et al 1999 Dev Biol 208:513.

X-Ray Sensitivity: ▶X-ray repair, ▶X-ray caused chromosome breakage, ▶nuclear size

X-Ray Therapy: ▶radiation therapy

X-Rays: Ionizing electromagnetic radiation emitted by the cathode tubes of Röntgen machines within the range of 10^{-11} and 10^{-8} m wavelength (see Table X1). The shorter ones (hard rays) have greater penetration and lower ionization density while the longer wavelengths (soft rays) have reduced penetration and denser dissipation of the energy. Hard rays cause more discrete lesions to the genetic material, soft rays are expected to produce greater chromosomal breakage. The spectrum of the radiation may be controlled by filters. The effectiveness of the filters depends on the attenuation of the radiation by the nature of the filter. The fluence of the radiation can be defined as $I = (I_0)e^{-\mu x}$ where I = fluence at a certain depth x ; I_0 = the fluence rate at the surface and μ = the specific attenuation coefficient and μ/ρ is mass attenuation coefficient (ρ = density of the absorbing material). At photon energy MeV = 0.1, the mass attenuation coefficients (cm^2/g) are for aluminum (0.171), iron (0.370), lead (5.400), water (0.171) and concrete (0.179). ▶cathode rays, ▶ionizing radiation, ▶X-ray repair, ▶Compton effect, ▶radiation hazard assessment, ▶radiation protection, ▶radiation effects, ▶Ku

XRCC: The genes XRCC2 (7q36.1), XRCC3 (14q32.3), XRCC4 (5q13-q14) and XRCC5 (Ku70, 2q35) in humans along with RAD51 (15q15.1, 17q11-q12) and DMC control recombination and repair. XRCC1 stimulates human polynucleotide kinase and promotes the repair of single-strand DNA breaks. XRCC3 protein, in concert with RAD51C, facilitates

homologous pairing and recombinational repair. ▶X-ray repair, ▶RAG, ▶RAD, ▶Ku, ▶DNA repair, ▶DMC, ▶XLF; Whitehouse CJ et al 2001 Cell 104:107; Masson J-Y et al 2001 Proc Natl Acad Sci USA 98:8440; Brenneman MA et al 2002 Mol Cell 10:387.

Xrn1p: An exonuclease degrading RNA beginning at the 5' end.

XREF: Cross-referencing model organism genes with human disease and other mammalian phenotypes. ▶databases

XRS: Mutation conveys radiation sensitivity, DNA double-strand break repair and V(D)J recombination. ▶DNA repair, ▶V(DJ); Matheos D et al 2003 J Cell Sci 116:111.

X-SCID (X-linked severe combined immunodeficiency): ▶SCID

XSL (XSLT): A software for transforming XML documents. ▶XML; <http://www.org/TR/xslt>.

X-Stain: A fluorochrome which stains the X chromosome differently from other chromosomes. ▶chromosome painting, ▶FISH

XX Males: A normal condition in birds and some other species, but rare 5×10^{-5} condition of it is a male mammalian (human) births. The recurrence risk is, however, about 25%. Most of them (90%) have a X chromosome—Y chromosome short arm translocation. Their phenotype and infertility resemble those of Klinefelter syndrome cases although the afflicted persons tend to be shorter in stature. Their distinction from hermaphrodites requires the use of an appropriate, fluorochrome-labeled cytogenetic probe for the critical Y chromosomal segment. ▶sex determination, ▶sex chromosomal anomalies in humans, ▶Klinefelter syndrome, ▶hermaphrodite; Vidal VP et al 2001 Nature Genet 28:216.

XXX: ▶triplo-X, ▶metafemale, ▶sex chromosomal anomalies in humans

XXY: ▶Klinefelter syndrome, ▶sex chromosomal anomalies in humans

Xylan: This is poly(β -D-xylopyranose[1→4]) polysaccharide of plant cell walls. The enzyme xylanase facilitates maize pollen tube penetration into silk by xylan hydrolysis (Suen DF, Huang HC 2007 J Biol Chem 282:625). ▶silk

Xylella fastidiosa: A bacterium that causes citrus variegated chlorosis which affects a broad spectrum of crop species. It has a 2,679,305 bp sequenced genome and two plasmids (51158 bp and 1285 bp). (See Nature 406:151).

Table X1. Thickness of the protective shield needed in mm using lead, depending on voltage and amperage of the X-radiation

| Kilo Volt | milliAmpere | | |
|-----------|-------------|------|------|
| | <5 | 5–10 | 30 |
| 50 | 0.5 | 0.6 | 0.7 |
| 125 | 1.5 | 3.0 | 3.5 |
| 250 | 6.0 | 7.0 | 8.0 |
| 400 | 16.0 | 18.0 | 21.0 |

Xylem: The transporting tracheid vessels of plants carrying nutrients and water from the roots toward the leaves. ►vascular tissue, ►phloem, ►proteoglycan

Xylene ($C_6H_4[CH_3]_2$): Synonymous with xylol, this highly flammable and irritant, narcotic liquid is used as a solvent in microtechnique. The permissible threshold of vapors in the air is 100 ppm.

Xylene Cyanole FF: ►tracking dyes

Xylose (wood sugar, $C_5H_{10}O_5$): An epimer of aldopentoses. It is used in the tanning industry, as a diabetic carbohydrate food, and in clinical tests of intestinal absorption. ►epimer

Xylulose ($C_5H_{10}O_5$): An intermediate in the pentose phosphate pathway which accumulates in the urine of pentosuric patients (see Fig. X7). ►pentose phosphate pathway, ►pentosuria

Figure X7. D-Xylulose

XY Body: ►sex vesicle

XYY: ►sex chromosomal anomalies in humans

Historical vignettes

AH Sturtevant commented on human genetics in 1954 (Science 120:405)

“Man is one of the most unsatisfactory of all organisms for genetic study. The time interval between successive generations is long, at best individual families are too small to establish ratios within them, and the test-matings that a geneticist might want cannot be made. Obviously no geneticist would study such a refractory object, were it is not for the importance that a knowledge of the subject has in other fields.”

Holger Breithaupt remarked in 2002 (EMBO Reports 3:391)

“Now imagine if Bush, Watson, Venter or Steffánsson had had to have their proposals passed by a democratically elected committee. Most likely, their obviously great ideas would have died an early and lonely death.”

Calvin B Bridges (1889–1938) was one of the most talented geneticists of all time. Most everybody can identify him as the founder of cytogenetics through his studies on nondisjunction, or with his work on salivary maps. Fewer people remember that he initiated the currently used gene symbols in *Drosophila*. Bridges also discovered the basic types of chromosomal aberrations:

“The general term ‘deficiency’ is used to designate the loss or inactivation of an entire, definite, and measurable section of genes and framework of a chromosome. A case of deficiency in the X chromosome of *Drosophila ampelophila* [currently *melanogaster*] occurred in September 1914, and has given rise to a whole series of

correlated phenomena. The first indication of this deficiency was the occurrence of a female which had failed to inherit from her father his sex-linked dominant mutant ‘bar,’ though she inherited in a normal manner his sex-linked recessive mutant ‘white.’ This female, when bred, gave only about half as many sons as daughters, the missing sons, as shown by the linkage relations, being those which had received that X which was deficient for bar” (*Genetics* 2:445, 1917).

Two years later Bridges reported duplications and translocations in the Abstracts of the Zoological Society (published in *Anatomical Record*):

“... a section of the X-chromosome, including the loci for vermilion and sable, became detached from its normal location in the middle of the X-chromosome and became joined on to the ‘zero’ end (spindle fiber) of its mate. For certain loci this latter chromosome carries two sets of genes—those present in the normal location and also the duplicating set. If a male carries the recessive genes for vermilion and for sable in the normal loci and the wild-type allelomorphs in the duplicating loci, he is wild-type in appearance precisely as though he were an XX female heterozygous for vermilion and sable. ...

“A third case is the transposition of a piece of the second chromosome to the middle (spindle fiber) of the third chromosome. The genes of this duplication piece show linkage to both the second and the third chromosome at the same time” (*Anat. Record* 15:357–358, 1919).

The basis of a crossover reducer as an inversion of the third chromosome of *Drosophila* was identified by Alfred H. Sturtevant (1891–1970) in 1926 (*Biol. Zbl.* 46:697).

Y

Y: The symbol of pyrimidines in nucleic acid sequences.

Y Box Proteins: Members of a family of transcription factors that bind to an inverted CCAAT box (Y box) that activates genes involved in cell proliferation and growth. Y box proteins interact with other proteins and modulate transcription. The absence of mouse MSY2 protein causes infertility due to developmental defects in gametogenesis in otherwise healthy-appearing male and female animals (Yang J et al 2005 Proc Natl Acad Sci USA 102:5755). (See Ladomery M, Somerville J 1995 Bioessays 17:9).

Y Chromosome: One of the sex chromosomes present in males (XY) generally. However, in some species (birds, insects, fishes) females are XY and males may be XX or XO. In organisms with homogametic males their chromosomal constitution is commonly identified as WW. In the majority of the species the Y chromosome has only genes for sex differentiation or sex determination. These genes in the non-recombinant (NRY, ~35 Mb) part are involved in sex and fertility determination whereas the other Y chromosomal genes have homologies with a common segment of the X chromosome (Xq21, 3.4 Mb with two genes) as well as sequences scattered in autosomes. Some X-transposed sequences are degenerate and contain 27 pseudogenic homologs of the X chromosomal genes. It was earlier held that the major part (~95%) of the Y chromosome lacked homology to the X chromosome and was thus unable to recombine with the X chromosome. Recent research, however, has revealed that this male-specific region (MSY, 8 Mb in the short and 14.5 Mb in the long arm) is flanked on both sides by pseudoautosomal sequences where recombination is actually a normal and frequent occurrence (Skaletsky H et al 2003 Nature [Lond] 423:825). The MSY also includes the so-called ampliconic sequences (high density of genes and repeats) with highly conserved tracts maintained by gene conversion. Of the eight large palindromes at least six contain testes determining genes. The MSY includes 156 transcription units in its euchromatic sequences. Further, 78 of the protein-coding units correspond to nine different MSY-specific gene families, encoding at least 27 distinct proteins or protein families. The TTY2 gene family includes at least 26 members arranged in tandem repeats. They are transcribed in the testis and in the adult kidney but some of them are not translated. Evolutionists have suggested that the general low gene number is a consequence of the absence of recombination. R.A. Fisher assumed that

the absence of recombination and genes is due to the fact that recombination would mess up the system of sex determination and would lead to intersexes. The diminution of the gene content of the Y chromosome has been attributed to Muller's ratchet. Molecular markers for the Y chromosome (>250) are increasing and it is now possible to trace paternal lines of evolutionary descent on the basis of variations in these chromosomes. This analysis is analogous to the use of mtDNA for the development of evidence for (mitochondrial) Eve's origin (Su B et al 1999 Am J Hum Genet 65:1718). Data on the Y chromosome should be carefully evaluated in pedigree analysis because the paternity may be equally likely for grandfather, brothers, cousins, etc., in the same family or even illegitimate male relatives. On the bases of the Y chromosomal constitution, 10 lineages appear to account for more than 95% of the current European human populations. The distribution of the Y haplotype shows more geographic than linguistic diversity because language influences were acquired more frequently than genes. The diversity of the human Y chromosome is lower than that of any other chromosome. The diversity between the human Y chromosome and that of the chimpanzee is larger (1.78%) than between the whole genomes where the difference is 1.23% (Kuroki Y et al 2006 Nature Genet 38:158). The Y chromosome of *Drosophila pseudoobscura* has no homology to that of *D. melanogaster* (Carvalho AB, Clark AG 2005 Science 307:108). ►sex determination, ►SRY, ►recombination variations of, ►Muller's ratchet, ►Eve foremother of molecular mtDNA, ►human evolution, ►F_{ST}, ►mutation rate, ►holandric genes, ►UEP, ►azoospermia, ►chimpanzee; for Thomas Jefferson's paternity analysis see Nature [Lond] 396:27; Nature [Lond] 397:32 and the rare K2 type Y chromosome (King TA et al 2007 Amer J Phys Anthropol 132:584; Owens K, King M-C 1999 Science 286:451; Kayser M et al 2001 Am J Hum Genet 68:173; Stumpf MPH, Goldstein DB 2001 Science 291:1738; Underhill PA et al 2001 Ann Hum Genet 65:43; Tilford CA et al 2001 Nature [Lond] 409:943; Hurles ME et al 2002 Genetics 160:289; Bachtrog D, Charlesworth B 2002 Nature [Lond] 416:323; Jobling MA, Tyler-Smith C 2003 Nature Rev Genet 4:598.

YAC: Refers to yeast artificial chromosome vectors equipped with a yeast centromere and some (*Tetrahymena*) telomeres in a linear plasmid containing selectable markers, ARS (autonomously replicating sequence) for the maintenance and propagation of eukaryotic DNA inserts in cloning of larger than 200 kb size sequences. YACs play an important role in identifying contigs in physical mapping of larger genomes, as well as in situ hybridization, map based gene isolation, etc. The rate of instability of YAC has been estimated to be about 2%. In mitotic yeast cells

YACs behave like other chromosomes. Meiosis can be analyzed by tetrads although recombination appears to be reduced. YACs may be maintained through some cell divisions in the mouse cytoplasm and behave like *double minute* chromosomes or they may be integrated into the mouse chromosomes. ▶anchoring, ▶contigs, ▶YAC library, ▶in situ hybridization, ▶chromosome walking, ▶pulsed field gel electrophoresis, ▶DM; Peterson KR 1999 Methods Enzymol 306:186; Brown WR et al 2000 Trends Biotechnol 18:218; Adam G et al 1997 Plant J 11:1349; Ragoussiz J, Monaco AP 1996 Methods Mol Biol 54:157, see Fig. Y1.

YAC Library: Contains large restriction fragments of genomic DNA cloned in YAC vectors and separated by pulsed field gel electrophoresis. A YAC library generally comprises 100 to 250 kb (or larger) size DNA fragments in multiple (at least five) copies if possible, covering the entire genome of an organism. Selecting the appropriate YAC clone for the purpose of finding the region of interest, the YAC library in yeast colony filter hybridization experiments is probed by RFLPs, PCR, inverse polymerase chain reaction probes,

plasmid rescue or by other means. ▶YAC, ▶contigs, ▶pulsed field gel electrophoresis, ▶colony hybridization, ▶RFLP, ▶PCR, ▶inverse polymerase chain reaction, ▶plasmid rescue, ▶probe, ▶genome project; Larin Z et al 1997 Mol Biotechnol 8:147.

YAK (*Bos grunniens*): This is a “wild ox” and also an Asian draft animal, $2n = 60$.

YAM (*Dioscorea* spp): A tropical food crop. The Asian and African species are $x = 10$ but the American are $x = 9$. The actual chromosome numbers vary from diploid to decaploid.

Yama: A Ced-3-like protease, also known as CPP32β. ▶apoptosis

Yang Cycle: The pathway of biosynthesis of ethylene from 2-keto-4-methylthiobutyrate (KMB)→ S-adenosyl-L-methionine (AdoMet)→5'-methylthioadenosine (MTA)→5'-methylthioribose (MTR)→5'-methylthioribose-1-phosphate (MTR-1-P)→KMB. AdoMet is then converted to 1-amino-cyclopropane-1-carboxylic acid (ACC) by ACC synthase and ACC oxidase generates ethylene. ▶ethylene,

Figure Y1. Top: A circular yeast plasmid with *Tetrahymena* telomeres. A segment of the pBR322 prokaryotic plasmid contains the replicational origin and the *Amp^R* gene (selectable in *E. coli* for ampicillin resistance). The *ARS* (autonomous replication sequence), cloned centromere of yeast chromosome 4 (*CEN 4*), restriction enzyme recognition sites where the plasmid can be opened for insertion and later ligation are shown. The *TRP1* (tryptophan) AND *URA 3* (uracil) genes of yeast serve to ascertain that both arms are present and the transformant can synthesize tryptophan and uracil. A piece of the plasmid between the two Bam sites and also the yeast *HIS* (histidine) gene are deleted. Because of the pBR322 sequences, this vector replicates in *E. coli* as well as in eukaryotic cells. All details are not shown and the diagram is not to scale. Other YAC vectors are similar but not identical with this model. Bottom: Completed linear YAC. (Modified after Burke DT et al 1987 Science 236:806)

Yeast Replicating Vectors (Yrp): These carry autonomously replicating sequences (ARS), have moderate stability and relatively low copy number, and they may be integrated into chromosomes. ▶vectors

Yeast Transformation: Can involve a number of different changes in the yeast chromosome at the site of transformation. (See Fig. Y3, ▶transformation genetic fungal transformation).

Yeast Transposable Elements: ▶Ty, ▶Ω

Yellow Crescent: Cytoplasmic motions in the fertilized ascidian embryo may generate a yellowish area that is broken up and shared by the cleavage cells thus revealing the origin of the differentiating cell lineage.

Yellow Fever: A viral (*Flaviviridae*) tropical disease primarily caused by the *Aedes aegypti* mosquito. Symptoms include high fever, headache, aching muscles, vomiting and backache and may be followed by shock, bleeding, kidney and liver failure. Liver failure causes jaundice (giving yellow fever its name). The fatality rate is ~50%. Preventive measures are avoiding exposure to mosquito bite and vaccination. Infants under the age of 6 months, pregnant women, immunocompromised persons and people allergic to egg should not be vaccinated. The spherical virions (40–50 nm) covered by a polyhedral capsid are decorated by small spikes. The RNA genetic material of the

Figure Y3. The various mechanisms of transformation and recombination between plasmid and chrosomal DNA in yeast. Gene 2' is an auxotrophic marker; gene 2 is a prototrophic homologue; 1' and 3' are flanking chromosomal sequences homologous to 1 and 2 in the plasmid with a Col E1 or other replicator. (Modified after Hinnen, Botstein & Davis in *Molecular Biology of the Yeast Saccharomyces*, Strathern, et al., eds. 1981 Cold Spring Harbor Lab. Press, Cold Spring Harbor, NY.)

virus consists of a single long open reading frame of 10,233 nucleotides, which can encode a polypeptide of 3,411 amino acids. The structural proteins are located within the amino-terminal 780 residues of this polyprotein; the remainder of the open reading frame consists of non-structural viral polypeptides. This genome organization implies that mature viral proteins are produced by post-translational cleavage of a polyprotein precursor (Rice CM et al 1985 Science 229:726).

Yep: ►yeast episomal vector

YEPD: Refers to yeast-peptone-dextrose culture medium.

Yersinia: A group of gram-negative bacteria responsible for bubonic plague (characterized by enlarged lymph nodes [bubo]), gastroenteritis, etc. in rodents and humans acquired through fleabites. Generally, but not always, infectiveness of the flea carriers may be blocked during the early stages of the incubation period (Eisen RJ et al 2006 Proc Natl Acad Sci USA 103:15380). The sequenced genome of *Y. pestis* includes a 4.65 Mb chromosome and three plasmids of 96.2, 70.3 and 9.6 kb. It contains 150 pseudogenes. The genome shows frequent insertion sequences and intragenic recombinations. The bacteria secrete the Yop protein that targets primarily dendritic cells, macrophages and neutrophils of the immune system but rarely the B and T lymphocytes (Marketon MM et al 2005 Science 309:1739). YopJ acetylates and inhibits MAPK kinase activation and inhibits NF- κ B signaling, thus disarming the innate immune system. YopJ acts as an acetyltransferase, using acetyl-CoA, and modifies critical serine and threonine residues in the activation loop of MAPKK6 and prevents phosphorylation (Mukherjee S et al 2006 Science 312:1211). Yersinia protein kinase A (YpkA) disrupts the eukaryotic actin cytoskeleton. Its Rac1 binding domain mimics the host guanine nucleotide dissociation inhibitors of Rho GTPases (Prehna G et al 2006 Cell 126:869). Pneumonic plague development requires the presence of plasminogen-activating protease (Lathem WW et al 2007 Science 315:509). ►virulence, ►biological weapons, ►plague, ►plant vaccines, ►herpes, ►cytoskeleton, ►Rac, ►RHO; Parkhill J et al 2001 Nature [Lond] 413:323; Hinnebusch BJ et al 2002 Science 296:733; Cornelis GR 2002 Nature Rev Mol Cell Biol 3:742; genome: <http://bbrp.lnl.gov/bbrp/html/microbe.html>.

YES: Refers to the yeast – *E. coli* shuttle vector. ►shuttle vector; Elledge SJ et al 1991 Proc Natl Acad Sci USA 88:1731.

YES1 Oncogene: This is in human chromosome 18q21. Its protein product is homologous to that of Roux'

sarcoma virus (SRC) and it is also a protein tyrosine kinase. In association with other proteins (YAP), it acts as a transcriptional co-activator. ►tyrosine kinases, ►oncogenes, ►palmitoylation

Y-Family DNA Polymerases: These are error-prone enzymes such as the prokaryotic UmuD'₂C (pol v), Din B (pol IV) and the yeast proteins Rev1 (cooperating with pol ζ) and Rad30. They copy damaged DNA efficiently, make frequent incorporation error ($\sim 10^{-1}$ to 10^{-3}), rely on mispairing, use mismatches, misaligned templates, etc. Pol η is defective in xeroderma pigmentosum-V. Pol θ incorporates nucleotides opposite purines much more efficiently and faithfully than against pyrimidines. Human Pol θ incorporates dCTP opposite template G through the G.C + Hoogsteen base pair (Nair DT et al 2005 Structure 13:1569). It has the ability to bypass deaminated cytosine but it is error prone when the DNA is undamaged and it inserts G opposite to T or U templates; it appears to be responsible for somatic hypermutation. Human Pol θ replicates the DNA by Hoogsteen base pairing (Nair DT et al 2004 Nature [Lond] 430:377). Pol κ is activated by an arylhydrocarbon receptor (benzo[a]pyrene) and may be a repair enzyme by bypassing DNA lesions but it may insert A across abasic sites. The Rev1 polymerase uses a protein template. ►DNA repair, ►error-prone repair, ►DNA polymerases, ►error in replication, ►X family of DNA polymerases, ►Rev1, ►Hoogsteen pairing; Goodman MF 2002 Annu Rev Biochem 71:17; Rattray AJ, Strathern JN 2003 Annu Rev Genet 37:31.

yIF-2: Refers to the yeast eIF-5B; it is homologous to the prokaryotic IF2. ►eIF-5B

Yin Yang (YY1, NF-E1): A multifunctional zinc finger transcription factor of growth factors, hormones and cytokines. YY1 is also a potential negative regulator of the tumor suppressor p53 (Sui G et al 2004 Cell 117:859). ►DNA-binding protein domains, ►animal hormones, ►cytokines; Santiago FS et al 2001 J Biol Chem 276:41143.

Yin Yang Haplotypes: These two haplotypes display differences in each SNIPs. ►haplotype, ►SNIPs; Zhang J et al 2003 Am J Hum Genet 73:1073.

Yin-Yang Crosses: A QTL is mapped by crossing to strains A and B. New strains are expected to segregate in crosses with one (A) or the other (B) and thus QTL

fine mapping becomes feasible. ►QTL; Shifman S, Darvasi A 2005 Genetics 169:849.

Y-Linked: ►holandric gene

Yohimbine: An alkaloid produced by African plants of the *Rubiaceae* and *Apocynaceae* families; their extracts have been used as an adrenergic blocking medicine for arteriosclerosis and hypertension. It is supposedly an aphrodisiac (see Fig. Y4). ►ferritin, ►aphrodisiac; Morales A 2001 World J Urol 19(4):251.

Figure Y4. Yohimbine

Yolk: The complex nutrients embedding the animal egg. ►egg, ►vitellogenin

YPD: ►yeast proteome

YPD: A yeast nutrient medium containing g/L yeast extract 10, glucose 20, Bacto-Peptone 10 or 20.

YPGE: A nutrient medium containing yeast extract (10 g), Bacto-Peptone (10 g), glycerol (20 g) and ethanol (10 g) per liter of H₂O.

YPL.db (Yeast Protein Localization database): <http://ypl.tugraz.at>.

YPT: A homolog of Sec and RAB. ►Sec, ►RAB

Y RNAs: These have a phylogenetically conserved secondary structure consisting of at least three stems and small internal loops. In humans, Y1, Y3, Y4 and Y5 have been identified but their function is unclear. It is suspected that they regulate ribosomal protein synthesis.

Yrp: ►yeast replicating vectors

YT Blood Group: Coded in human chromosome 7q.

YT Bacterial Medium: H₂O 900 mL, bacto-tryptone 16 g, bacto-yeast extract 10 g, NaCl 5 g, pH 7.0 (adjusted by 5N NaOH), filled up to 1 L and diluted to half before use.

Yttrium (Y): An extremely rare metal; the ⁹⁰Y has a half-life of 64 hours and has been used for internally exposing cancerous tissues to β-radiation. ►ionizing radiation, ►isotopes, ►magic bullet

Figure Y5. Production of (YY) all-male asparagus

Yuasa Oncogene: Its human homolog is in chromosome 7.

YY Asparagus: By regeneration of plants from microspores and chromosome doubling, plants can be

obtained with this chromosomal constitution. The practical advantage of this vegetatively reproducible plant is the approximately 30% higher yield of edible spears. (See Fig. Y5, for embryogenesis, somatic).

Historical vignettes

Oscar Hertwig on genetics: “The hypothetical idioblasts... are according to their different composition, the bearers of different properties, and produce by direct action, or by various methods of cooperation, the countless morphological and physiological phenomena, which we perceive in the organic world. Metaphorically they can be compared to the letters of the alphabet, which, though small in number, when combined form words, which in their turn, combine to form sentences or to sounds, which produce endless harmonies by their periodic sequence and simultaneous combination.” (*The Cell*, Macmillan, New York, 1895, page 340)

Although Friedrich Miescher a contemporary of Mendel described nucleic acids in 1871, there remained an almost century-long disconnect between his findings and Mendel's. It is interesting to note that the nature of the mechanisms of fertilization remained an enigma even to Miescher. “So werden wir von allen seiten genöthigt, es mit Bestimmtheit auszusprechen: *Es giebt keine spezifischen Befruchtungsstoffe*. Die chemischen Thatsachen haben secundäre Bedeutung; sie sind einem höheren Gesichtspunkt untergeordnet.” (Miescher. 1874). [There is no specific fertilization-substance. The chemical realities have secondary meaning; they are subject to a higher order of strategy.] (Miescher F 1874 Die Spermatozoen einiger Wirbelthiere. Ein Beitrag zur Histochemie. Verhandl Naturforsch Ges Basel 6, (issue I):138–208.)

Z

Z (or *z* or *Z* score): The standard normal probability density function calculated by the formula:

$$Z = \frac{1}{\sigma\sqrt{2\pi}} e^{-(Y-\mu)^2/2\sigma^2}$$

where *Y* is the normal variate, $\pi \cong 3.14159$ and $e \cong 2.71828$, μ is the mean and σ is the standard deviation. The *z* values are generally read from statistical tables. *Z* indicates the height of the ordinate of the curve and thereby the density of the items. ► [standard deviation](#), ► [normal distribution](#), ► [confidence intervals](#), ► [F distribution](#)

Z Buffer: Na₂HPO₄·7H₂O 0.06 M, NaH₂PO₄ 0.04 M, KCl 0.01 M, MgSO₄·7H₂O 0.001 M, β-mercaptoethanol 0.05 M, pH 7. Do not autoclave it.

Z Chromosome: Refers to the sex chromosome present in both sexes of a species with heterogametic females (thus comparable to the X chromosome). Males are ZZ and females are WZ. ► [W chromosome](#), ► [sex determination](#)

Z Disc (Z-disk): ► [sarcomere](#)

Z Distribution: A statistical device for testing the significance of the differences between correlation coefficients in case the null hypothesis is not $r = 0$. The relation of *z* to *r* has been elaborated by R.A. Fisher as $z = (1/2)[\ln(1 + r) - \ln(1 - r)]$ and its standard error as $\sigma_z = \frac{1}{\sqrt{(n-3)}}$. For routine calculations, tables are available in statistical textbooks. ► [covariance for correlation coefficient](#)

Z DNA (zig-zag DNA): A relatively rare left-handed double helix that may be formed in the short (8–62 bp) regions of alternating purines and pyrimidines (ATGTGTGT, GCATGCAT). The polyGC.polyGC sequences are most favorable for B→Z transition. In some species CA/TG repeats are most conducive for Z DNA formation. Alternating purine-pyrimidine tracts may also modulate the transcription in a plus or minus direction. Base sequences near the transcription starting point favor the formation of Z DNA and it may stimulate transcription. Nucleosomes are not formed in the Z DNA tract, thus facilitating the access of transcription factors. In some genes, however, such as in the constitutive nucleolin gene, Z DNA in the promoter downregulates transcription. Vaccinia virus is no longer lethal in mice if the Z DNA binding site is lost. Four families of proteins bind to the crystal structure of Z DNA: ADAR1, an editing enzyme, LM1, an interferon inducible

protein, E3L, a pox virus virulence factor and an orthologue of PKR, interferon-induced protein kinase. Z DNA occurs in a dynamic state; it is formed and then it can revert to the B form of the DNA. There is a transition point between the common B and Z DNA forms (see Fig. Z1). The handedness changes abruptly from left to right by a sharp turn of the phosphate backbone. At the transition point an adenine (A0) and thymine (T0), respectively, are extruded as shown by the crystal structure (Ha SC et al 2005 Nature [Lond] 437:1183). B-Z DNA conformational polymorphism is optically detectable on single-walled carbon nanotubes in whole blood, tissue and within living mammalian cells (Heller DA et al 2006 Science 311:508). The figure shows space-filling models (modified after Dickerson RE et al 1982 Science 216:475). In mammals, Z DNA forming sequences induce a high level of chromosomal instability by generating double-strand breaks and large deletions. These deletions at the Z DNA may raise the incidence of certain cancers by increased transcription (Wang G et al 2006 Proc Natl Acad Sci USA 103:2677). In bacteria, the Z DNA related deletions are short.

Figure Z1. The heavy black line represents the sugar-phosphate backbone

An alternating deoxycytidine-deoxyguanosine dinucleotide repetitive sequence [d(CG)*n*] can potentiate transcription in yeast when placed approximately three helical turns (28 bp) upstream of the cytochrome *c* 1 (CYC1) TATA box. Transcriptional activation by the d(CG)₉ repeat sequence depends on

the Z conformation. The activation is core promoter-specific and most effective when situated 28 bp or below upstream of the TATA box. Changing the distance between the d(CG)₉ repeat sequence and the TATA box modulates the extent of activation. Linker-DNA region is formed at the Z DNA structure with two flanking nucleosomes. Z DNA creates an open chromatin state at the promoter by displacing nucleosomes from its environs and establishing the boundaries of its neighboring nucleosomes (Wong B et al 2007 Proc Natl Acad Sci USA 104:2229). ▶DNA types, ▶ADAR, ▶RNA editing, ▶nanotechnology; Liu R et al 2001 Cell 106:309; Rothenburg S et al 2001 Proc Natl Acad Sci USA 98:8985; Rich A, Zhang S 2003 Nature Rev Genet 4:566.

Z Inactivation: The Z chromosome of birds has the same role in sex determination as the X chromosome in mammals yet its genes are not inactivated in homogametic individuals. ▶dosage compensation; Kuroda Y et al 2001 Chromosome Res 9:457.

Z Linkage: Refers to genes syntenic in the Z chromosome. ▶X-linked

Z Ring: Same as Fts Z ring. ▶tubulin

Z RNA: This left-handed molecule may occur in double-stranded RNA and is similar to Z DNA. ▶Z DNA, ▶ADAR; structure and origin: Placido D et al 2007 Structure 15:395.

Z Scheme: An additional (zig-zag) scheme to generate enough ATP by photosynthesis. Through a two-step process (photosystem I and II) an electron passes from water but there is not enough energy in a single quantum of light to energize the electron directly and

efficiently all the way from PS II to the top of PS I and make NADP⁺. The leftover energy makes pumping H⁺ possible across the membranes to capture some light energy for synthesizing ATP. The redox state of plastoquinone regulates the transcription of genes encoding the reaction center proteins of both photosystem I and II. ▶photosystems; Prince RC 1996 Trends Biochem Sci 21:121; Allen JF 2003 Science 299:1530; Allen JF, Martin W 2007 Nature [Lond] 445:610, see Fig. Z2.

Z Score: ▶Z

z Value: The natural logarithm of the ratio of two estimated standard deviations. ▶variance

ZAG (Zn-α₂-glycoprotein): Though this resembles MHC class I heavy chain molecules, it is different because it cannot bind β₂-microglobulin. It occurs in the majority of body fluids and is apparently involved in inducing fat loss in adipocytes. It accumulates in breast cancer cells and other cells in serious distress (cachexia). ▶MHC, ▶HLA, ▶obesity; Kennedy MW et al 2001 J Biol Chem 276:35008.

Zanier-Roubicek Syndrome: ▶ectodermal dysplasia, ▶hypohidrotic

ZAK (zipper sterile-α motif kinase): A mixed lineage kinase (MLK) in signal transduction.

ZAP-70 (zeta-associated protein 70): A cytosolic protein tyrosine kinase expressed only in T cells and natural killer cells. By binding to phosphorylated ζ-chains of the CD3 T cell antigen-receptor complex, it assists in the activation of T cells. Its defect may lead to severe combined immunodeficiency. ZAP-70 tyrosine kinase signals to the CXCR4 chemokine receptor

and thus regulates the migration of T lymphocytes. It seems to be involved in arthritis in mice. ►SHP-1, ►CD3 T cell, ►CXCR, ►killer cell, ►immunodeficiency, ►tyrosine kinases, ►retroviral restriction factors; Ottoson NC et al 2001 J Immunol 167:1857; Sakaguchi N et al 2003 Nature [Lond] 426:454, crystal structure: Deindl S et al 2007 Cell 129:735.

ZBP1 (Zipcode binding protein): ►mRNA migration

Zea mays (L.): ►maize

Zeatin (6[4-hydroxy-3-methyl-cis-2-butenylamino]purine): Refers to a cytokinin plant hormone. In *Agrobacterium* T-DNA-located *ipt* gene encodes an isopentenyl transferase that mediates the synthesis of transzeatin and isopentenyl adenosine. In plant tissue culture media it is a commonly used alternative to kinetin, benzylamino purine or isopentenyl adenosine. ►plant hormones

Zebra: *Equus quagga* $2n = 44$; it can form hybrids with both horses (*Equus caballus*, $2n = 64$) and donkeys ($2n = 62$). *Equus grevyi*, $2n = 46$ (see Fig. Z3); *Equus zebra hartmanniae*, $2n = 32$. The Zebra duiker (*Cephalophus zebra*, $2n = 58$) is not a member of the Equidae family but is the male member of a bovine species.

Figure Z3. *Equus grevyi*

ZEBRA (Zta): A non-acidic activator protein of the lytic cycle of the Epstein-Barr virus; it promotes the assembly of the DA complex (TFIID-TFIIA) of transcription factors. ►transcription factors, ►open transcription complex, ►DA

Zebrafish (*Brachydanio rerio*, $2n = 50$): A 3–4 cm tropical freshwater fish; the genome size is about 2×10^9 bp (see Fig. Z4). It is easy to breed and becomes sexually mature in 2–3 months (4 generations/year).

The embryogenetic pattern is laid down in 12 hours, and it is well suited for the analysis of developmental pathways and cell lineages in this small vertebrate. Hundreds of eggs are laid externally. The embryos are transparent and permit observation of gastrulation, development of the brain and heart, etc. Haploids survive for several hours and mutants are available. About 600 genes involved in its development have been identified, and in 1998 a 3350 cM map of 3.3 cM resolution became available. The zebrafish genome has extensive homology to that of humans. ►EP, ►medaka, ►GloFish; Fishman MC 1997 Methods Cell Biol 52:67; Detrich HW III et al 1999 (Eds.) The zebrafish: Biology. Academic Press; radiation hybrid map: Geisler R et al 1999 Nature Genet 23: 86; Hukriede NA et al 1999 Proc Natl Acad Sci USA 96:9745; Woods IG et al 2000 Genome Res 10:1903; Shin JT, Fishman MC 2002 Annu Rev Genomics Hum Genet 3:311; hematopoiesis: de Jong JLO, Zon LI 2005 Annu Rev Genet 39:481; human disease model: Lieschke GJ, Currie PD 2007 Nature Rev Genet 8:353; <http://zebra.sc.edu>; <http://zfish.uoregon.edu/ZFIN/>; <http://zfin.org>; <http://depts.washington.edu/fishscop/>; <http://www.tigr.org/tdb/tgi.shtml>; <http://zfin.org>; <http://zf-espresso.tuebingen.mpg.de>.

Figure Z4. Zebrafish

Zebu (*Bos indicus*): $2n = 60$. ►Santa Gertrudis cattle

Zein: A prolamine protein in maize (homologous to gliadin in wheat) that may account for up to 50% of the grain proteins. It does not have high nutritional value (and is therefore undesirable) because of the low lysine and tryptophan content. It is deposited in zein bodies at the place of synthesis. In the high-lysine maize varieties (*opaque*, *floury*) prolamines are very low and non-prolamine proteins increase. ►high-lysine corn, ►glutenin

Zeitgeber: A rhythmic external signal for the circadian change. ►circadian rhythm

Zeitnehmer: An internal signal for rhythmicity in response to the zeitgeber or even in its absence. ►circadian rhythm, ►zeitgeber

Zellweger Syndrome (ZS): A brain-liver-kidney (cerebrohepatorenal) recessive disease involving human chromosome 7q11.12-q11.13; but over a dozen other loci may have similar effects. The basic defect is due to peroxisome anomalies. ►microbodies, ►neuro-muscular diseases, ►chondrodysplasia punctata, ►cataract, ►pseudo-Zellweger syndrome

Zero, Absolute: The minimum lowest temperature; Kelvin 0° = Celsius $- 273.15^{\circ}$.

Zero Time Binding: Refers to the status of reassociation of two single-strand palindromic DNAs at the beginning of an annealing kinetics experiment. These are the fastest reassociating fractions because they are repeats and are close to each other. ►c₀t curve

zeste (z, chromosome 1.10 of *Drosophila*): The protein kinase product apparently alters the chromatin structure and affects the expression of *w*, *Ubx*, *dpp* by attaching to their promoters. Its action bears similarity to *Polycomb*. The zeste-white3 complex regulates the spindle attachment to the cortical actin. ►w locus, ►Polycomb; McCartney BM et al 2001 Nature Cell Biol 3:933.

Zeugopodium: Corresponds to the radius, the ulna, the tibia and the fibula.

ZFX (human chromosome Xp22.3-p21.2): This Zinc finger protein similar to Zfy was believed to be responsible for feminization of some XY individuals and gonadal dysgenesis. It is not a primary sex determining protein. ZFX escapes inactivation in humans but not in mice. It controls pluripotency of stem cells. ►pluripotency; Palmer MS et al 1990 Proc Natl Acad Sci USA 87:1681.

ZFY (zinc finger Y, Yp11.3): A sequence in the Y chromosome assumed to be involved in the maturation of testes or sperm. A 729 bp intron located immediately upstream of the Zinc finger exon shows no or very little sequence variation in worldwide human samples. ►Zinc finger, ►ZFX

Zidovudin: ►AZT

zif: ►NGFI-A

Zig-Zag Inheritance: ►criss-cross inheritance

Zig-Zag Model of Chromosome Fiber: Radiation-induced DNA breaks revealed fragment sizes of 78 bases, which corresponds to one turn of the DNA around the nucleosome. Additional peaks between 175 and 450 bases reflect the relative position of the nearest neighbor nucleosomes. Calculations and other considerations seem to support a zig-zag model of the chromatin fiber rather than a simple helical

model (Rydberg B et al 1998 J Mol Biol 284:71). ►solenoid

Zinc Finger Nucleases: These are limited-specificity nucleases that can recognize certain DNA sequences and cause small deletions at selected targets. The Zn fingers prefer guanine-rich tracts, particularly 5'-GNN-3' triplets. Each nuclease unit may have three fingers and each grabs one triplet, i.e., a total of nine bases. The dimeric structure of the nuclease cleaves both strands in a tract lying between the G-rich sequences (see Fig. Z5). Non-homologous end-joining may follow the double-strand breaks and thus somatic and germ line mutations may occur. Zinc finger nucleases are associations of the Zinc finger with, e.g., a FokI restriction endonuclease (target GGATG(N)_{9/13}) and can thus be targeted to specific mammalian genes (Porteus MH 2006 Mol Ther 13:438) or can be used to repair specific defective genes in plants by targeted homologous recombination (Wright DA 2005 Plant J 44:693). ►non-homologous end-joining, ►gene therapy; Bibikova M et al 2002 Genetics 161:1169; Miller JC et al 2007 Nature Biotechnol 25:778.

Figure Z5. Diagram of a dimeric (A and B) zinc-finger endonuclease and its mode of cleavage (at the green lines) of DNA. The subunits recognize the DNA sequence by the green shaded square domain. The zinc-fingers bind to the G-rich repeats. (Modified after Bibikova M et al 2002 Genetics 161:1169)

Zinc Fingers: These are binding mechanisms of transcription factors and other regulatory proteins containing tandemly repeated cysteine and histidine molecules and they fold in a “finger-like” fashion cross-linked to Zn. They contain other highly conserved amino acids—phenylalanine (F), leucine (L) and tyrosine (Y). Some Zinc finger proteins bind the RNA to the DNA. About 0.7% of the proteins in budding yeast and the nematode *Caenorhabditis elegans* contain Zn finger motifs; in yeast most commonly 2/molecule and in *Caenorhabditis* up to 14/molecule. Using DNA microarray designs, putative Zn finger transcription factor binding sites can be identified. By designing new Zinc finger motifs, specific regulation of gene expression is possible (Reynolds L et al 2002 Proc Natl Acad Sci USA 100:1615). Zinc is an essential

element for life and it is a cofactor for several enzymes. ▶hormone receptor, ▶DNA-binding protein domains, ▶microarray hybridization, ▶acrodermatitis enteropathica, ▶ZFY, ▶RING finger, ▶binuclear Zinc cluster, ▶Cys₄ receptor, ▶GATA, ▶LIM; Rubin GM et al 2000 Science 287:2204; Bulyk ML et al 2001 Proc Natl Acad Sci USA 98:7158; Pabo CO et al 2001 Annu Rev Biochem 70:313; binding tools: <http://www.scripps.edu/mb/barbas/zfdesign/zfdesignhome.php>; Zn finger protein design: <http://bindr.gdcb.iastate.edu/ZiFiT/>.

Zinc Knuckle (Zf-CCHC): A Zn-binding motif commonly found in the nucleocapsids of retroviruses (e.g., HIV) and in regulatory proteins of diverse eukaryotes. Its sequence is CX₂CX₄HX₄C where X can be different amino acids. These protein motifs are involved in binding RNA or single-strand DNA. (See Le Thuy et al 2001 Mol Cell Biol 21:8346).

Zinc Ribbon Fold (CXXC(H)-15/17-CXXC): This is present in diverse binding proteins. ▶binding proteins, ▶transcription factors

Zinc Ring Finger: ▶RING finger

ZIP1, ZIP2: Protein factors that mediate phosphorylation of potassium ion channels by protein kinase C. ▶protein kinase, ▶ion channel

Zipcode: ▶mRNA migration

Zipper Domain: Refers to part of dimeric DNA-binding proteins where the two subunits are held together by repeating amino acid residues; in the other parts the subunits are separated from each other. ▶leucine zipper

Zoidogamy: In this fertilization takes place by motile antherozoids. ▶siphonogamy

Zollinger-Ellison Syndrome (Wermer syndrome MEN 1): A multiple endocrine adenomatosis (neoplasia) encoded in human chromosome 11q13. ▶adenomatosis multiple endocrine

Zona Pellucida: A yolky layer around the mammalian egg. Zona pellucida domains are present in dauer larvae of nematodes and mechanotransducers in *Drosophila* and are involved in other functions. The domain ~260 amino acids have eight conserved cysteines near the carboxyl end and are often glycosylated. ▶fertilization [animals], ▶vitelline layer, ▶egg, ▶dauer larva, ▶mechanosensory genes; Jovine L et al 2002 Nature Cell Biol 4:457; Jovine L et al 2005 Annu Rev Biochem 74:83.

Zonoskeleton: This includes the scapula, the clavicle and the hip bones.

Zonula Occludens: A tight cell junction mediated by ZO proteins associated with a 210–255 kDa membrane-tied guanylate kinase. ▶MAGUK, ▶ELL; Meyer TN et al 2002 J Biol Chem 277:24855.

Zoo Blot: Southern hybridization experiments with probes derived from a variety of different species to test potential homologies. (See Rijkers T, Ruther U 1996 Biochim Biophys Acta 1307:294).

Zoo FISH: Fluorescent in situ hybridization maps for several species to study the evolutionary relations of their chromosomes. ▶FISH

Zoonosis (zoonotic infection): Animal pathogens transferred to humans (by e.g., grafts, food) may lead to the development of new human diseases under natural conditions. ▶grafting in medicine, ▶acquired immunodeficiency, ▶xenotransplantation, ▶Dengue fever, ▶Ebola virus, ▶Pox Virus, ▶West Nile Virus, ▶sleeping sickness, ▶influenza, ▶SARS, ▶encephalopathies, ▶mycobacteria, ▶plague, ▶laboratory safety; Weiss RA 1998 Nature Med 4:391.

Zoospore: This is a motile (swimming) spore.

Zootype Hypothesis: According to this, HOX-type homeobox genes are present in all metazoa. ▶homeotic genes

ZP1, ZP2, ZP3: Refer to zona pellucida glycoproteins. ▶fertilization, ▶zona pellucida

ZPA (zone of polarizing activity): Determines the anterior/posterior differentiation of the limbs and is located behind AER in the limb bud. ▶AER, ▶limb bud

ZPK: Denotes a leucine zipper protein kinase. ▶DNA-binding protein domains

ZPR: Refers to zinc finger protein binding to the epidermal growth factor receptor. ▶zinc fingers, ▶EGFR

Zta: ▶ZEBRA

Zuotin: Z DNA and tRNA binding protein of yeast. It has structural homology with DnaJ and is functionally related to the mammalian chaperone MIDA1, required for cellular growth. ▶chaperones, ▶DnaK, ▶MIDA1; Braun EL, Grotewold E 2001 Mol Biol Evol 18:1401.

Zwischenferment: ▶G6PD

Zwitterion: A dipolar ion with separated positive and negative poles.

ZygDNA: It has been reported that 0.1 to 0.2% of the eukaryotic DNA may not be replicated until

late leptotene–zygotene. This delayed replication involves dispersed 4–10 kb stretches and it has been assumed that these segments (ZygDNA) code for genes with products aiding chromosome pairing. It is assumed that a leptotene (L) lipoprotein is involved in the delayed replication. (L) ▶ [meiosis](#); Hotta Y et al 1985 Cell 40:785.

Zygomeres: Refer to hypothetical initiators of chromosome pairing in the DNA.

Zygomorphic: A structure of bilateral symmetry, like a snapdragon flower (see Fig. Z6).

Figure Z6. Zygomorphic. Courtesy of Dr. Z. Schwarz-Sommer

Zygonema: Denotes the chromosome at the zygotene stage. ▶ [meiosis](#), ▶ [zygotene stage](#)

Zygosis: Twins can be identical (monozygotic, MZ) or non-identical (dizygotic, DZ). The distinction is not always simple because dizygotic twins (like any siblings) may show several identical features, depending on the genetic constitution (consanguinity) of the parents. If the probability of monozygosis between twins with identity in a genetic marker is designated as $P(A_1/B)$ where A_1 and B are different markers and the probability of the twins being either dizygotic or erroneously assumed to be monozygotic is: $1 - P(A_1/B)$. The calculation may be based on the formula:

$$P(A_1/B) = \frac{1}{1 + [Q \times L]}$$

where Q is the dizygotic:monozygotic proportion in the population (DZ/MZ), and L = likelihood ratio of the conditional probabilities for DZ and MZ twins would be identical for a particular genetic condition. The conditional probabilities that if one of the twins is of a particular dominant type, the second would also be of the same type at dizygosis is $0.5 - 1.0$, and at monozygosis 1.0. In the case of recessive markers, these probabilities are 0.25 and 1.0, respectively. The probabilities also depend on the genetic constitution of the parents. Recessive markers may be expressed only if both parents carry that particular allele. If either of the parents is homozygous for a dominant marker, then both twins must carry that marker, irrespective of zygosity. L can be computed as $L = \frac{P[DZ]}{P[MZ]} L_1 \times L_2 \dots L_n$ where $\frac{P[DZ]}{P[MZ]}$ is the empirical probability of the DZ:MZ proportions in the general population, and $L_1 \times L_2 \dots L_n$ are the conditional probabilities for the genetic markers 1 to n used, either 0.25 or 1.0. Further complications may arise if either the penetrance or expressivity of the markers varies. The DZ:MZ proportions may vary generally from 0.65:0.35 to 0.70:0.30 but are somewhat different in various ethnic groups, depending on the age of the mother, the use of fertility drugs and artificial insemination, etc. DNA markers, either by RFLP or the PCR method of typing, can better resolve the problem than using blood types or other genetic analyses. ▶ [conditional probability](#), ▶ [likelihood](#), ▶ [RFLP](#), ▶ [PCR](#), ▶ [DNA fingerprinting](#), ▶ [twinning](#), ▶ [monozygotic](#), ▶ [dizygotic](#), ▶ [concordance](#), ▶ [discordance](#)

Zygosity: ▶ [zygosis](#)

Zygospore: This is formed by the fusion of two spores or two multinucleate gametangia. ▶ [heterothallism](#), ▶ [homothallism](#), ▶ [gametangia](#)

Zygote: A cell resulting from the union of two gametes of opposite sexes. ▶ [gamete](#)

Zygotene Stage: This stage of meiosis occurs when the homologous chromosomes (supposedly) begin to synapse. The pairing usually begins at the termini and proceeds toward the centromeric region. At this stage the synaptonemal complex is detectable by electron microscopy. The intimate bivalent pairing appears to be a requisite for chiasma formation as well as for genetic recombination (see Fig. Z7). ▶ [meiosis](#), ▶ [chiasma](#), ▶ [synaptonemal complex](#), ▶ [association point](#), illustration after K. Bela \hat{r} .

Figure Z7. Zygotene

Zygotic Combinations: ►Punnett square, ►allelic combinations

Zygotic Gene: During embryo development this gene is involved in the early control of differentiation in contrast to the maternal effect genes, which are transcribed from the maternal genome and their product is transused to the embryo. ►maternal effect genes, ►morphogenesis

Zygotic Gene Activation: After fertilization there is a transition from maternal to zygotic control of development. This process in mouse begins after G₂ of the one cell embryo (Schultz RM 1993 Bioessays 15:531). In humans it seems to be somewhat delayed.

Zygotic Induction: Usually the integrated λ prophage is inherited as an integral gene of the bacterial chromosome. However, when a lysogenic Hfr cell carrying λ is crossed to a *non-lysogenic* F⁻ recipient, the prophage leaves the chromosomal position (induction) and becomes an infectious vegetative phage after replicating to about 100–200 particles. After zygotic induction, only the markers transmitted before the position of the prophage has changed are recovered in the recombinants. Zygotic induction does not occur if the F⁻ cells are *lysogenic*, irrespective of whether or not the Hfr is lysogenic. The F⁻ recipient is immune to superinfection by free λ phage and it cannot support the vegetative development of the chromosomal λ phage transmitted by the Hfr donor. This indicates that the F⁻ cytoplasm carries an immunity substance or a repressor. ►lysogeny, ►Hfr, ►F⁻, ►lysogenic repressor, ►lambda phage; Hayes W 1965 The genetics of bacteria and their viruses. Wiley, New York.

Zygotic Lethal: A genetic factor that permits the function of the gametes but kills the zygote. The two systems presented here occur in the plant *Oenothera*, which carry translocation complexes. Letters printed in gray indicate lack of zygote

| | | Male gametes | |
|----------------|---|--------------|----|

| | | A | B |
| Female gametes | A | AA | AB |
| | B | AB | BB |

Figure Z9. Gametic lethal factors A and B are unable to form selfed zygotes and only the heterozygous embryos are viable. Only the female can contribute viable B gamete and the male produces viable A gametes

formation (see Figures Z8 and Z9) ►translocation, ►complex heterozygote, ►translocation [in animals], ►*Oenothera*

Zymogen: An inactive enzyme precursor. ►regulation of enzyme activity

Zymogram: Electrophoretically separated isozymes are identified in the electrophoretic medium (starch, agarose) by supplying a chromogenic substrate in situ and this reveals the position of the functionally active enzyme bands. ►electrophoresis, ►isozyme

Zymolase: This hydrolyzes 1→3 glucose linkages such as those existing in yeast cell walls; it is not an exactly defined mixture of proteins extracted from *Athrobacter luteus*.

Zymosan: A cell wall extract with a variety of components interfering with the C3 complement. ►complement; Ohki K et al 2001 Immunol Cell Biol 79:462.

Zymotype: This is an electrophoretically determined pattern of enzymes (proteins) which is characteristic of individuals or group of individuals. ►isozymes, ►electrophoresis, ►zymogram

Historical vignettes

“I have a rather strange feeling about our DNA structure. If it is correct, we should obviously follow it up at a rapid rate. On the other hand it will at the same time be difficult to avoid the desire to forget completely about nucleic acid and to concentrate on other aspects of life.” (*JD Watson's letter to Max Delbrück on March 22, 1953. Quoted after HF Judson 1979 The Eighth Day of Creation. Simon and Schuster, New York, p. 229*)

Evelyn Witkin (2002) in reminiscing about the pre-Watson and Crick and Hershey and Chase era at the Cold Spring Harbor Laboratory writes (*Annu. Rev. Microbiol.* 56:1):

“Although Avery et al (1) had demonstrated in 1944 that the genetic material is DNA, the prevailing attitude at Cold Spring Harbor had been respectful skepticism. Some suggested that the transforming DNA in their experiments had activated genetic information already present or somehow caused a directed mutation. Others believed that the minuscule trace of protein still contaminating the DNA was the active agent. Delbrück declared DNA to be a “stupid” molecule, incapable of carrying genetic information.”

In 1962 Francis Harry Compton Crick, James Dewey Watson and Maurice Hugh Frederick Wilkins were jointly awarded the Nobel Prize in Physiology or Medicine “for their discoveries concerning the molecular structure of nucleic acids and its significance for information transfer in living material”.

In 1969 the Nobel Prize in Physiology or Medicine was shared by Max Delbrück, Alfred D Hershey and Salvador Luria.

Appendix

Gregor Mendel among fellow monks in Alt Brunn *circa* 1862. In front of him sits Abbot FC Napp who accepted him to the Augustinian Order in 1843. In 1868, Mendel became Abbot and Anselm Rambousek (standing second from left) followed him in that position in 1884 after his death. This photograph sheds some light on the characters of his fellows. While some look bored or argumentative, Mendel studies a fuchsia plant. Fortunately, he did not continue with this ornamental plant with chromosome numbers $2n = 22, 55, 66$ and 77 , that frustrated others before and after his time. He had perhaps good luck but his genius was needed for recognizing his luck. (The photograph is the courtesy of Dr. V Orel.)

Reviews of Author's Books

NATURE (Lond) 302:169 "...sections dealing with molecular genetics ... are remarkably clear and up to date." "...this one is one of the best textbooks of general genetics". "The book is extremely well illustrated..."

THEORETICAL AND APPLIED GENETICS 66:38 "...a balanced treatment of almost all genetics disciplines"

HEREDITY 33:123 "...unusually good value."

QUARTERLY REVIEW OF BIOLOGY 74:74 "The author clearly met his goal: to facilitate communication and understanding across all biological sciences". "...this book should prove very useful as a quick desk reference for students, professionals and non-professionals."

AMERICAN JOURNAL OF MEDICAL GENETICS 83:145 "He undauntedly covers the entire field of contemporary genetics including not only the classical areas of formal genetics and cytogenetics but also the latest global molecular advances and their applications". "I found the contents very useful..."

ACTA PÆDIATRICA 87:1211 "The strength of the book lies in its brief explanations ... it is invaluable for anyone interested in this rapidly evolving area, including scientists, teachers, students, and laymen."

ANNALS OF INTERNAL MEDICINE 130:168 "This book is a valuable reference tool and will be of interest to a wide audience. Other books, including glossaries and dictionaries of genetics are available but are more limited in coverage".

ANNALS OF THE ENTOMOLOGICAL SOCIETY OF AMERICA 91:894 "The preparation of a book like this is a massive task. If it is done well, it can provide a valuable central resource to information that might otherwise take a lengthy search to uncover". "In this case ... the overall effort has been very successful."

HortScience 33:1274 "The book is attractive and user-friendly." "This manual is by far the best I have used".

MUTATION RESEARCH FORUM 1999 May "... this book is a true information warehouse". "The words in this book came through as if someone were talking directly to me." "The investment ... is worth it."

JOURNAL OF PHYTOPATHOLOGY 147:623 "This giant volume is recommended to those who are in contact with the genetic aspects of questions in their

field of research or practice." "The most important feature of this book is that all concepts are explained not just defined." "The style is clear even for the beginner".

ACTA AGRONOMICA HUNGARICA 47(2):237 "...although a number of dictionaries or glossaries of genetics already exist, this ... is quite different from the others in-as-much as it is much more comprehensive, and not only defines the concepts but explains them in concise plain language"... "fills a void".

CHOICE 1998, 36-1563 "...outstanding compendium of genetics"... "Highly recommended for biologists".

GENOMICS & PROTEOMICS 2003 (Nov./Dec):56. "useful resource...50% more information than in the first edition".

GENOMICS REVIEWS (2004, Internet). "Excellent resource."

Book News (2004, Internet). "By authoring the work single-handedly (clearly a labor of love) Redei (emeritus, U. of Missouri) could maintain a consistency of approach and avoid redundancy and yet still attain impressive breadth and depth in a compact reference."

GENOMICS & PROTEOMICS (2003, Nov/Dec):56. "...useful resource... 50% more information than in the first edition".

NÖVÉNYTERMELÉS (2003, 52:724). "...excellent tool...I recommend it to the attention of everybody". (translated from Hungarian)

CHOICE (2004, 882:41-2549). "...an expanded version of the highly acclaimed Genetics Manual... reflects recent developments in genetics, molecular and cell biology, genomics and proteomics." ... "valuable... Recommended".

BOOKWORKZ (2004, Internet). "...incomparable reference...thorough coverage of modern genetics, genomics, and proteomics".

E-STREAMS (2004, 7[1]:2969). "This is a highly usable item and provides effective and efficient access to relevant topics."

THE SCIENCE ADVISORY BOARD (2004, Internet). "... the best got even better." "This book is indispensable, as a reference for research universities, for high schools, for public libraries, and because of the relatively modest price ...it is affordable for individuals too."

BIOspectrum (2004, 10:653). "it is truly wonderful". "Most students, scientists, all geneticists, including human geneticists, the general public interested in natural sciences, teachers and journalists can benefit from it to a great degree. It is a must for larger biological libraries!" (translated from German).

CLINICAL CHEMISTRY (2004, 50:1719–1720). "... the book has an encyclopedic quality, far surpassing a dictionary." "...many readers will find themselves engrossed in this fascinating book." ... "This is a wonderful book..."

PROTEOMICS (2004, 4:544–545). "Once you start reading this book it is difficult to put down. It is a valuable source of such a breadth of information that would surely be difficult to find elsewhere." "...a highly recommended one-stop resource for medics, grad students and researchers."

GENETIC ENGINEERING NEWS (2004, 24(6), March 15): "...genomics and post-genomics terms, including concepts, theories, and applications, explained

concisely for novices and comprehensive enough for those with expertise."

REFERENCE REVIEWS (2004, 18(62004):43–44): "excellent volume"... "is a readable, accessible, well thought out and extremely useful reference book."

MICROBE (Amer. Soc. Microbiol.) (2004, May): "It is impressive that a single author can put together a dictionary of this size and make it useful to the general scientific reader."... "Rédei's definitions are accurate"... "[he] is a clear winner."

THE CHEMICAL EDUCATOR (2005, 10(6):56–57) "Rédei has eminently succeeded in attaining his goal." "Numerous cross-references link the short entries into a most encyclopedic, up-to-date text."... "gold mine of valuable...information."

MEDICAL REFERENCE SERVICES QUARTERLY (2006, 2[(1):104) "...high quality reference book" "this is the most comprehensive..."

About the Author

George P. Rédei is Professor Emeritus at the University of Missouri, Columbia. Born in Vienna, Austria he completed his formal education in Hungary. Rédei is affiliated with the University of Missouri since 1957 where he has taught formal courses in basic genetics, analytical genetics, history of genetics and genetic engineering. He has been visiting professor at several leading institutions in Germany, Hungary and China.

Rédei has introduced *Arabidopsis* to genetic research in the USA and published seminal research papers on classical, molecular, population genetics and history of genetics in *Science*, *Nature*, *Cell*, *Genetics*, *Canadian Journal of Genetics and Cytology*, *Journal of Heredity*, *Genome*, *Experientia*, *EMBO Journal*, *Proceedings of the National Academy of Sciences USA*, *Genes &*

Development, *Molecular and General Genetics*, *Development*, *Mutation Research*, *Annual Review of Genetics*, *Advances in Genetics*, *Bibliographia Genetica*, *Biochemical Genetics*, *Theoretical and Applied Genetics*, *Biologisches Zentralblatt*, *Protoplasma*, *Plant Physiology* and other international journals. More than 50,000 students have used his textbook, *Genetics* (translated also into many foreign languages). Preceding editions and translation of the present volume have been bestsellers.

Rédei is a foreign member of the Hungarian National Academy of Sciences since 1990 and in 2004 the University of Missouri named a section of the new Life Sciences Building in his honor.
